## ACKNOWLEDGEMENT

I wish to acknowledge the support of many persons without whom this research and my thesis would not have been accomplished. First, of course, I would like to express my deepest gratitude and sincere appreciation to Assoc. Prof. Dr. Chaitip Wanichanon, my major advisor, and Prof. Dr. Prasert Sobhon, my co-advisor, for their kindness, valuable advice, guidance, and encouragement throughout this work. I am so impressed with their generous donation of time whenever I asked them to explain or discuss problems concerning my study and thesis.

Also, I am deeply grateful to Prof. Dr. Maleeya Kruatrachue who gave me the opportunity to study under her direction. I truly appreciate her encouragement and help during years of my study. I am especially indebted to Assoc. Prof. Dr. Prapee Sretarugsa for her valuable guidance, attention, criticism, support and suggestion. I am also thankful to Miss Somjai Apisawetakan and Mr. Vichai Linthong for their unending supports throughout this entire project. Special thanks are extended to Miss Kulathida Chaithirayanon and Miss Sasiporn Panasophonkul for their general helps.

I also would like to thank Miss Pornrut Rabintossaporn, Mr. Ardool Meepool, Mr. Worawit Suphamungmee, members of the Electron Microscopy Laboratory and the entire staff of the Anatomy Department who provided not only efficient and competent support.

I would also like to acknowledge the financial support for this research and my stipend from the Thailand Research Fund (Senior Research Scholar Fellowship to Prof. Dr. Prasert Sobhon).

Last, but not least, I wish to thank my parents and everybody in my family for their support and encouragement. Very special thanks and deepest appreciation are given to M.R. Sam-aungvarn Lamsam and her family who support my education from the very beginning. I apologize in advance for those I may have inadvertently omitted in these acknowledgements.

The aim of this thesis was to study the ovotestis histology, ultrastructure and pattern of chromatin organization in male germ cells during spermatogenic processes in *A. fulica* by light and transmission electron microscopy. The ovotestis was composed of numerous small tubules which were separated from the surrounding connective tissue by the basement membrane. Each tubule contained various stages of developing male and female germ cells, Sertoli cells, and follicular cells. Based on their size, shape and chromatin condensation pattern, the male germ cells could be classified into a spermatogonium (Sg), six stages of primary spermatocytes, *i.e.*, leptotene (LSc), zygotene (ZSc), pachytene (PSc), diplotene (DSc), diakinesis (DiSc) and metaphase (MSc) spermatocytes, secondary spermatocyte (SSc), ten stages of spermatids (St<sub>1-10</sub>), and two stages of spermatozoon (Sz<sub>1-2</sub>). Sg was a spherical-shaped cell; its nucleus contains mostly euchromatin and few small blocks of widely scattered heterochromatin. The heterochromatin blocks became larger and more numerous in LSc and ZSc, which was due to the winding of 30-nm fibers around a single-dense line that was the axis of chromatin condensation. The euchromatin contained individual 30-nm as well as 10-nm chromatin fibers. ZSc also had synaptonemal complex, the tripartite structure. The heterochromatin blocks were enlarged to form a few pieces of chromosomes in DSc and DiSc. The two halves of chromosomes in DiSc were segregated, then moved to be aligned along the equatorial region in MSc. SSc was a round cell, derived from the division of MSc, whose nucleus contained large clumps of heterochromatin along the nuclear envelope and in the central area. St<sub>1-4</sub> had round-shaped nuclei which became progressively smaller and denser. During transition of SSc to St<sub>1</sub> the dense chromosomes were reorganized into evenly distributed 30 and 10 nm fibers. Thereafter, 30-nm chromatin fibers started to be condensed into heterochromatin blocks again in St<sub>2</sub> and St<sub>3</sub>. In St<sub>4</sub> the 30-nm fibers became homogeneously condensed throughout the nucleus. St<sub>5</sub> nucleus was gradually compressed on cephalo-caudal direction to become cup-shape and was indented further to assume an arrow or boomerang shape in St<sub>6</sub>, while 30-nm fibers were decreased in size to about 20 nm, and were straightened to form 14-16 nm fibers in St<sub>7</sub>. Then, the nucleus became a pear shape in St<sub>8</sub>. In St<sub>9</sub> and St<sub>10</sub> the nucleus started to elongate to form a tapered anterior end, and the chromatin was completely condensed. The straight chromatin fibers were packed into bundles about 120 nm in width which coalesced into dense crystal lattice-liked structure in the spermatozoa. The spermatozoon had a falciform-shape head that contains completely condensed chromatin in the crystal lattice conformation with dense individual 10-nm lines separated by the intervals of 3-4 nm. It was covered anteriorly by a small acrosome. The neck region was composed of centriolar complex surrounded by a rhomboid shape crystalline substance. The mid-piece consisted of axonemal-fibrous complex surrounded by the helical mitochondrial sheath. The end-piece consisted of only axonemal complex surrounded by the plasma membrane.

## CHAPTER I

### INTRODUCTION

The perfect terrestrial adaptation is found mostly in vertebrates and arthropods. Mollusks, which have come to live on land, are still dependent on a moist environment and are inactivated by drought and low temperature. This ability of the mollusks is related to some structural changes and considerable physiological adjustments which enable them to slump into inactivity that is most pronounced in hibernation and aestivation of land pulmonates. Pulmonates are essentially land and freshwater mollusks; they belong to one of the three subclasses of Gastropoda, the Pulmonata. The Pulmonata is divided into 3 orders: The Basommatophora with one pair of contractile cephalic tentacles bearing eyes at the base. The second order, Stylommatophora reaches the peak of pulmonate evolution; they are common terrestrial snails and slugs which usually have two pairs of invaginable tentacles with eyes at the tip of posterior pair. This genus of land snails include *Helix*, *Helicella*, *Cochicella*, *Bulimulus*, etc. The third order, the Systellommatophora includes many species of mostly tropical slugs. They possess two pairs of contractile tentacles with the eyes at the tip of the posterior pair. These slugs have neither an external nor internal shell (1).

*Achatina fulica*, the giant African land snail, belongs to the Phylum Mollusca, Class Gastropoda, Subclass Pulmonata, Order Stylommatophora, Suborder

Achatinacea, Family Achatinidae (2, 3). Members of this order are fully adapted to terrestrial environment and breathe by lung.

*A. fulica* is originally imported from Africa to North America, many Indo-Pacific Islands and East Asia (2). Since then it has spreaded widely and could be found everywhere, including Thailand. It is also prevalent in other Southeast and East Asia countries, including China, Taiwan and Japan where it is considered to be a serious pest problem of gardens and domestic crops because they consume a vast amount and many varieties of vegetation (2, 4). Although there have been efforts to process them into escargot, they are not much accepted as *Helix aspera* and *Helix pomatia*, species of land snails found in Europe such in Spain and France (2). However, if there is a good control of reproductive activity to get more amounts of products with the elimination of parasite infection, they can be escargots that have more economic importance. This snail is easy to keep in captivity, and it can be maintained on a herbivorous diet, eating both fresh and decaying vegetation. So it provides useful material for research in reproductive system. Interestingly, *Achatina* is hermaphrodite. It has a protandrous gonad in which oocytes and spermatozoa are produced simultaneously in close proximity. In order to control and improve the production of this snail, hence the basic knowledge of the reproductive biology of gonad needed to be considered more increasingly.

Most of previous studies have described about the pattern of their nervous system with relative small numbers of larger cells in the ganglions (5, 6, 7). But in the reproductive system, there have been a number of studies on spermatogenesis and oogenesis of various species of pulmonate snails (8, 9, 10, 11, 12). But concerning the details of similar information in *Achatina fulica* have been reported in a few

number (12). Therefore, the aim of this study was to investigate the morphology, histological characteristics, and cellular association firstly of male gamete cells in the gonad of *A. fulica* by light and electron microscopy.

## **CHAPTER II**

### **OBJECTIVES**

1. To investigate the histology, spermatogenic processes and cellular association within the ovotestis of *Achatina fulica* by light microscopy
2. To investigate the ultrastructural characteristics of various stages of the male gamete cells during spermatogenesis and spermiogenesis of *Achatina fulica* by transmission electron microscopy.
3. To investigate the organization and pattern of chromatin condensation during spermatogenesis and spermiogenesis by transmission electron microscopy.

## CHAPTER III

### LITERATURE REVIEW

All pulmonates are monoecious. Although they show functional protandry, but the reproductive system can fulfill the functions of male as well as female gametes. Concerning general morphology, the shell of *A. fulica* is narrow conoid and is approximately 2-3 inches in length (13). The color is variable, but usually consists of alternating brown and cream or white bands. The body is brownish grey in color. It comprises a head which has a terminal mouth, two pairs of invaginable tentacles and eyes at the top of hinder pairs, a visceral mass made up the gonad, digestive gland, stomach, and loops of intestine, and a large foot with creeping sole and the pedal gland that discharges and lubricates along its creeping pathway (1, 2, 3).

#### **Reproductive Biology**

*A. fulica* has a complex reproductive system. The gonad is called the "ovotestis" which usually appears white, yellow, orange, red or black according to species (14). In *A. fulica*, it appears as yellow mass, and is located at the apex of coiled shell where it is firmly embedded in the digestive gland (13). The pulmonates' ovotestes have been studied by many investigators. Such as in primitive basommatophorans were studied by Dancan (1) who found the first appearance of ovotestis as a solid cord of germinal epithelium when the snail was 5-mm long (1). Spermatogonia begin to appear about two weeks before the oogonia, when animal is fully mature, eggs and

sperms are present together (13). Initially, Pawson and Chase (1984), have studied the reproductive biology of this snail, and reported that the sexual maturity was reached at 5 months of age, with a peak in egg production between 210-270 days of age (15). Later in 1989, Ngowsiri, *et al.*, have performed more detailed study and also found that the ovotestis first appeared in 3-month-old snails and progressively increased in number as the snails reached the age of 7-8 months. However, when they reach older age, this number was decreased. In these snails, the male phase also occurred before the female phase, and when female phase became most active, the male phase decreased in function (14, 16).

The gonad consists of small units called "acini". Runham and Hogg (1979) have reported on the development of gonad of *Deroceras reticulatum*, a pulmonate snail, that the number of acini was increasing to 70-180 during differentiated stage (17). In later stages, the acini were increased in size and became lobes. Adult *A. fulica*'s ovotestis is composed of 5-7 lobes with about 1000-3000 acini in each lobe (13, 14, 15). Each acinus is completely lined at the basement membrane with the oocytes located at the periphery and each of them is covered by 3-4 layers of follicular cells except at the base (11, 13). As described above, the acini or tubules are compartmentalized into the female and male compartments. The female germ cells develop abuminally; they are separated from the male gamete cells by a continuous layers of the Sertoli cells, which has the cytoplasmic processes penetrating throughout the germinal epithelium (17, 18, 19). Thus, the male compartment is adjacent to the acinar lumen (10, 20). The pulmonate snail has internal fertilization. In *Lymnea stagnalis* (21), when the snail acts as a male during copulation, sperms are transported from the stores in seminal vesicle via the male duct, the prostate gland, vas deferens,

and penis into the vagina of the copulation partner. A small part of the transferred sperm is stored; the main part is digested in the bursa copulatrix (18, 22). And when the mature oocytes are ovulated, they are fertilized in the hermaphroditic duct near the carrefour, where this duct gives rise to male and female pathways.

### **Spermatogenic Process in *Achatina fulica***

The male gamete cells always occur in all the acini of terrestrial snail. The production of the male germ cells of pulmonate snail has been reported that; the primitive germ cells proliferate from germinal cells forming a discontinuous layer in germinal wall of each tubule, they undergo spermatogenesis or oogenesis at the original site of their proliferation (22). A cluster of spermatogonia may be derived from one primitive germ cell which develops around a Sertoli cell (15, 21, 22). The division and differentiation of the cells in each cluster are strictly synchronized (21, 23). Spermatocytes are progressively increased in size and number, and evenly become attached to the Sertoli cells at prophase stage (11, 22). Various stages of spermatogenesis and Sertoli cells have been studied in the pulmonate snails; such as a freshwater snails, *Biomphalaria glabrata* (11) and *Bulinus truncatus* (10) and the marine snail, *Littorina sikana* (8), and some of the other gastropods. These studies have invariably shown that the Sertoli cells are involved in the nutrition of male germ cells and phagocytosis of residual cytoplasm of late spermatids during spermiation (8, 10, 11). The Sertoli cells are connected by septate desmosomes, and they contain carbonic anhydrase, an enzyme involved in ion-exchange process (9, 23, 24). In 1989, Elsaadany (10) has suggested that the Sertoli cell of *Bulinus truncatus*, a

freshwater snail, has the morphological features of steroid producing cells which are involved in hormone production. Such information is still lacking in *A. fulica*.

A further consequence of this morphology of the ovotestis is that the ultrastructure of the male germ cells during spermatogenesis and spermiogenesis shows nuclei which undergo the process of condensation that starts in early spermatids and culminates in spermatozoa. The ultrastructural changes of various stage cells during early spermatogenesis in gastropods are generally classified into spermatogonia, five or six stages of spermatocytes and secondary spermatocyte based on the nuclear changes and the characteristics of chromatin during cell divisions (9, 10, 12, 23, 25). In 1991, Sretarugsa, *et al.* (12), reported the ultrastructural changes during spermatogenesis of *A. fulica* and the morphology of mature spermatozoa. They classified the cells in spermiogenesis into 4 stages based on the shape, chromatin appearance, and organization of cytoplasmic organelles. Stage I spermatid contained an uniformly-dense nucleus. Stage II spermatid had similar features to the previous stage, but the mitochondria were accumulated to one side of the cell. Stage III spermatid had a cup-shaped nucleus containing evenly distributed chromatin. Stage IV spermatid was characterized by a cone-shaped nucleus with dense chromatin rods and narrow intervening spaces. The mature spermatozoa consisted of three main parts: the elongated head with highly condensed chromatin, the middle-piece consisting of straight flagellum and helical mitochondria sheath, and the tail showing the outpocket of glycogen granules in the proximal part (12).

Chromatin condensation during spermiogenesis has been studied in *Murex brandaris* (27) which show distinct events such as the formation of granules (18-20 nm in diameter) which are arranged into fibers (10-15 nm in diameter) that are

transformed further into lamellae (17 nm thickness). Partial lamellar fusion decreases the thickness of each lamella to 11 nm. From other studies, the pattern of nuclear condensation has been described as “fibrillar-lamellar” type in internally-fertilized sperm of most meso- and all neogastropods, opisthobranchs and pulmonates (28, 29, 30, 31, 32, 33). This pattern of chromatin condensation was described in three successive phases: granular, fibrillar and lamellar structures, then finally become tightly packed in myelin-like whorls (26, 30, 31, 34). In contrast, the externally-fertilized sperm in primitive gastropods (33, 35, 36, 37, 38), scaphopods (39) and bivalves (40, 41) appears to be “granular” type. Initial report of the modified spermatozoa of *Achatina fulica* indicated that the chromatin condensation pattern belongs to the first type (34). It is interesting to investigate how DNA in the spermatids are packaged through various orders of chromatin organization.

Other structural changes which appear to be characteristics of mature sperm are the acrosomal formation and tail differentiation. The complex acrosome in gastropod was found in *Arion rufus*, (31); *Nucella lapillus* (42) and *Anguispira alternata* (43); it consists of a cylindrical structure with a membrane-bound vesicle. In other Stylommatophorans such as *Agriolimax reticulatus* (44), a typical acrosome could not be seen, but a finely granular homogeneous material is seen surround the apex of the nucleus (45). In contrast, only a single acrosomal granule can be observed near the nucleus in the slug, *Arion ater* (46).

Concerning the tail formation, common modification of the spermatozoon is the formation of mitochondria mid-piece. In many species the mitochondria increase in number and are spreaded down the flagellar axoneme. The pulmonate gastropods perhaps show the greatest degree of mitochondria modeling (26, 28, 45). As

maturation proceeds, mitochondria of *Achatina zebra* fuse in a continuous sheath around the axoneme, forming a mitochondrial derivative (28). Enclosed within this derivative and spiralling along the axoneme, is a compartment containing glycogen as has been reported in many Stylommatophorans and some Basommatophorans (47, 48, 49). The mitochondrial derivative and glycogen complex may not extend for to the entire length of the tail. The section without the mitochondrial derivative is known as the end piece (12, 29, 49).

Therefore, The aim of the present study was to investigate the ultrastructure of the cells in spermatogenesis process and spermatozoa, and to observe the pattern of chromatin fibers packing during spermiogenesis in *Achatina fulica*.

## CHAPTER IV

### MATERIALS AND METHODS

#### Collection of *Achatina fulica* Specimens

Adult *A. fulica* were collected from the natural habitat, such as garden surrounding houses or office building that they reside in abundance. Small pieces of fixed gonads were prepared for light microscopic observations by the procedures of paraffin and semithin methods, and the sections were observed under an Olympus Vanox microscope.

#### Procedure for Light Microscopy

The shells of the snails were removed and their ovotestes were cut and fixed in Bouin's fixative at 4°C overnight. They were washed in 70% ethyl alcohol to remove the Bouin's fixative. Then, they were dehydrated in a graded series of ethyl alcohol (70-100%) for 30 minutes each, cleared with dioxane, infiltrated and embedded in paraffin wax. Thereafter, the blocks of specimens were sectioned at 5-micron thickness, and finally stained with hematoxylin and eosin.

#### Procedure for Transmission Electron Microscopy

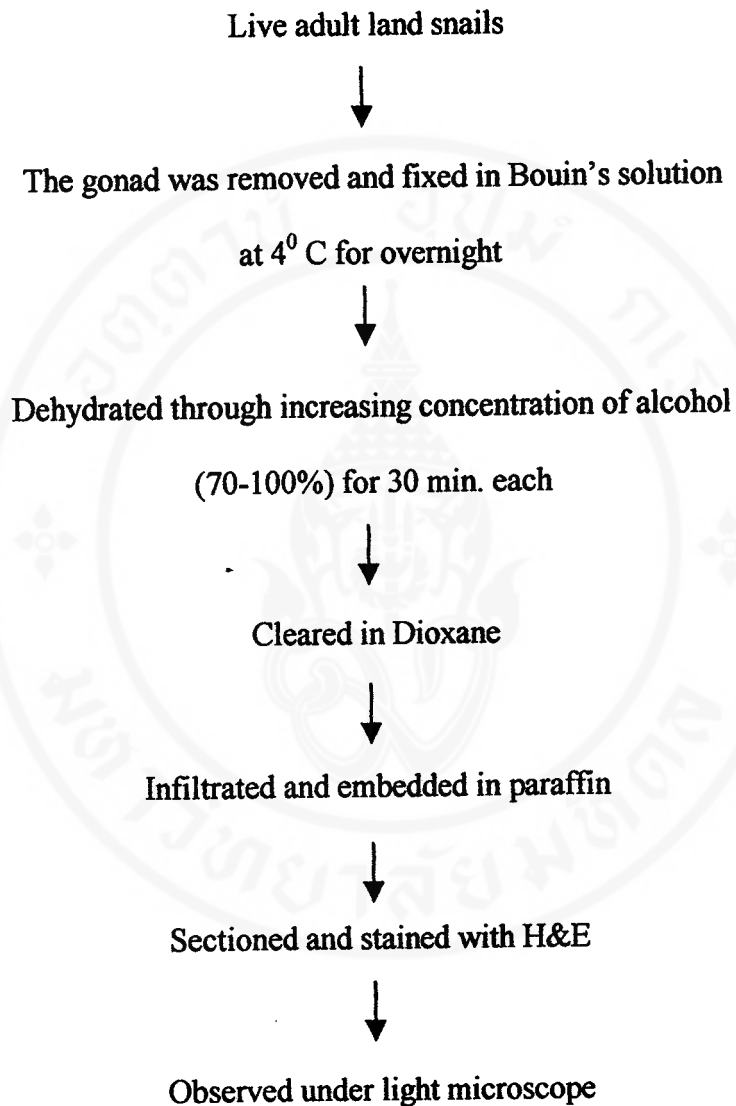

The ovotestes were cut and sliced into very small pieces and fixed in a solution of 4% glutaraldehyde plus 2% paraformaldehyde in 0.1M sodium cacodylate buffer at 4°C for overnight. Then the specimens were washed in 0.1M sodium

cacodylate buffer and postfixed in 1% osmium tetroxide in 0.1M sodium cacodylate buffer at 4<sup>o</sup> C for one hour at 4<sup>o</sup> C. Subsequently, the specimens were dehydrated in a graded series of ethyl alcohol (50-100%) for 30 minutes each, cleared in two changes of propylene oxide (PO), infiltrated in a mixture of propylene oxide and Aradite 502 resin at the ratio of 3:1 for two hours, 2:1 for one hour, and 1:2 for overnight. Then they were embedded in pure Aradite 502 resin, and finally polymerized at 30<sup>o</sup> C, 45<sup>o</sup> C and 60<sup>o</sup> C for 24, 48, 48 hours, respectively. Blocks of specimens were sectioned with a Sorvall MT-2 ultramicrotome using glass knives at 1 micron and 300-500 A<sup>o</sup> thickness. The thin sections were picked up with copper grids, stained sequentially with uranyl acetate and lead citrate, and then examined under a Hitachi H-300 transmission electron microscope operating at 75 KV. In addition, the semithin sections were stained with 1% methylene blue and observed under an Olympus Vanox microscope.

### **Procedure for Measurement of Chromatin Fibers**

Various stages of male germ cells in *Achatina fulica* were classified. The organizational level and pattern of chromatin condensation in the male germ cells from five animals were observed and measured. The images of each chromatin fibers in at least five nuclei were viewed via Kodak electron microscopic negative films and measured under a Nikon profile projector, based on Catalase Crystals (Agar Aids) magnification calibration.

## Paraffin Section Method

## Semithin and Thin Section Methods

## CHAPTER V

### RESULTS

#### **General Morphology of the Reproductive System in *Achatina fulica***

*Achatina fulica*'s body is enclosed in a yellow-brown right-handed coiled shell. It is 7 to 8 cm long and 4 to 5 cm wide, and consists of a head, 2 pairs of a visceral mass and a large foot with a creeping sole. The head bears 2 pairs of retractable tentacles, the anterior ones being shorter than the posterior. The posterior tentacles bear the eyes at their distal tips. (Figs. 1A-C). A small opening to the common genital duct is found below and slightly behind the base of the right posterior tentacle. This common genital opening could be found clearly during the breeding season (Figs. 1B; 2A, B). When copulation occurs, the intromittant muscular penis of one snail will be everted and inserted into the duct of its partner (Figs. 2A, B). *A. fulica* has a complex reproductive system, and its ovotestis is located in the inner coiled face of the digestive gland enclosed within the apex of the shell. It appears yellow in color. The gonad and the base of albumen gland are connected by the hermaphroditic duct (Figs. 3A, B). Beyond this, male and female gametes follow separate pathways. The male part has secretory organs, *i.e.*, the prostate gland, which is connected to the vas deferens that passes through the body wall and opens into the penis. The female part comprises of the uterus, oviduct and vagina (Figs. 4A, B).

## Gonadal Histology

The ovotestis is embedded in and mixed with the digestive gland. Histologically, the ovotestis consists of numerous small tubules which are separated from each other by a loose network of connective tissue (Figs. 5A-C). Each tubule contains various stages of developing male and female germ cells (Figs. 5B, D), Sertoli cells, and follicular cells. The oogenic cells commonly lie close to the basement membrane and are surrounded by thin processes of follicular cells. Spermatogenic cells, including spermatogonia, early and late stages of spermatocytes, aggregated in groups, make up the main mass of the germinal epithelium of each tubules (Figs. 5A-D), while the clusters of spermatozoa are found in the adluminal part. The heads of spermatozoa are usually embedded in the cytoplasm of large Sertoli cells which are situated on the basement membrane (Figs. 5C; 8E).

## Classification of Spermatogenic Cells

The spermatogenic cells appearing in the ovotestis could be classified into 19 stages according to the cell sizes, their structural features and chromatin condensation pattern as observed under the light and transmission electron microscopes.

**Spermatogonium (Sg)** is a spherical or oval-shaped cell 7 to 8  $\mu\text{m}$  in size. Its nucleus is round or ovoid with a diameter about 5 to 6  $\mu\text{m}$ . Under LM and TEM, the nucleus contains mostly euchromatin and small blocks of heterochromatin scattering throughout. It also possesses one or two very prominent nucleoli. The cytoplasm exhibits moderate to intense basophilia depending on the amount of ribosomes (Figs. 6A,

B; 9B); it also contains few developing rough endoplasmic reticulum, only a few mitochondria and small Golgi complex (Figs.9E, F). Within the nucleus, the chromatin fibers consist of 2 levels, *i.e.*, 10 and 30 nm fibers; the former appears as thin zigzag lines while the latter appears mostly as dense dots in cross sections, and thus assumed to be highly coiled (Fig. 9C, D; Table 1).

**Primary spermatocytes (PrSc)** consist of 6 stages, *i.e.*, leptotene (LSc), zygotene (ZSc), pachytene (PSc), diplotene (DSc), diakinetik (DiSc) and metaphase (MSc). The most distinctive differences among various stages of PrSc are the relative amount of euchromatin versus heterochromatin and the patterns of chromatin condensation.

**Leptotene spermatocytes (LSc)** (Figs. 6C; 10A, C) This spherical-shaped cell is larger than Sg with a diameter about 13-15  $\mu\text{m}$ , and it has a large round nucleus about 10  $\mu\text{m}$  in diameter. There are small blocks of heterochromatin scattered evenly throughout the nucleus. The nucleolus is also present, but it is smaller than that of Sg. The cytoplasm is stained light blue with methylene blue; thus, this cell has less basophilic cytoplasm than Sg. Under TEM, the euchromatic area contains 2 levels of chromatin organization, *i.e.*, the 30-nm fundamental chromatin fibers which mostly appear as dense dots in cross sections, and 10-nm fibers which appear as zigzag lines (Figs.10D-F). Moreover, there is the first appearance of thick dense lines that form the axis of chromatin condensation which could be found projecting from the nuclear membrane as well as scattering in the central area of the nucleus. Judging from the tight threading of 30-nm chromatin fibers around it, this structure is believed to be the initiation site of

chromosome condensation (Fig. 10C-F). The cytoplasm also contains abundant ribosomes, rough endoplasmic reticulum, increasing number of mitochondria and larger Golgi complexes (Fig. 10A-C).

**Zygotene spermatocyte (ZSc)** (Fig. 6D; 11A, B) This cell has approximately the same size as LSc. Under LM, it is distinguished from LSc by the heterochromatin which becomes increasingly thread- or cord-like. The nucleolus is still fairly prominent as that of LSc (Fig. 6D). The cytoplasmic basophilia is decreased. At TEM level, the nucleus contains increasingly dense heterochromatin blocks, each surrounding the longer axis of chromatin condensation, and the synaptonemal complexes which could not be found in LSc (Fig. 11C-F). The synaptonemal complex is distinguished from the axis of condensation by the tripartite structure that has a conspicuous central element separated from the two lateral elements by clear spaces which are traversed by straight filamentous elements. Chromatin fibers (30nm) from adjacent chromosomes are attached to the side of each lateral element of the synaptonemal complex (Fig. 11E). The cytoplasm has similar feature as that of LSc (Figs. 11A, B).

**Pachytene spermatocyte (PSc)** This cell still shows a round shape with smaller size than that of LSc (about 12-13  $\mu\text{m}$  in the cell and 8-9  $\mu\text{m}$  nuclear diameters). The nucleus of PSc is round and still contains fairly prominent nucleolus (Figs. 6E; 12A, B). Under LM, the nucleus contains heterochromatin that becomes condensed into long thick threads or cords that are entwined into loops radiating from the nucleolus (Fig. 6E). Under TEM, this chromatin appears as dense interconnecting clumps of heterochromatin cords that consist of closely packed 30-nm fibers (Figs. 12D, E; Table 1). The cytoplasm

also contains rough endoplasmic reticulum, large amount of well-developed mitochondria, and large Golgi complexes (Figs. 12A, C, F).

**Diplotene spermatocyte (DSc)** (Fig 6F, 13A-D) This cell is about 10-12  $\mu\text{m}$  in size. As revealed by LM, its nucleus (about 8  $\mu\text{m}$  in diameter) shows thicker threads of heterochromatin that are increasingly condensed and become more closely packed. Hence, the nucleus appears denser and darker than that of PSc, and the nucleolus disappears. Under TEM, the 30-nm fundamental chromatin fibers are packed more tightly and these packing occurs both within the nucleus and near the nuclear membrane. The features of cytoplasmic organelles still appear similar to those of earlier stages (Fig. 13A).

**Diakenetic and Metaphase spermatocytes (DSc and MSc)** At LM level, these stages of cells show large pieces of highly condensed chromatin that begin to be separated from each other in diakenetic stage (Figs. 6G, H), and move to be aligned at the equatorial region in metaphase stage when the nuclear membrane completely disappears (Figs. 6G, H). At TEM level, these stages exhibit the large chromatin blocks that are parts of the chromosomes, which are formed by the tight aggregation of individual 30 nm chromatin fibers (Fig. 14A). The organelles consisting mainly of RER and mitochondria appear in the cytoplasmic area surrounding the chromosomes which are no longer surrounded by the nuclear membrane (Figs. 13E, F; 14A, B; Table 1).

**Secondary spermatocyte (SSc)** assumes a more oval shape and becomes larger in size with diameter about 14-16  $\mu\text{m}$ , while the nuclear diameter is about 7  $\mu\text{m}$  (Fig. 6C). SSc is the result of the first meiotic division, and the cell is encountered infrequently.

Under LM, the nucleus shows 7 to 9 large clumps of heterochromatin along the nuclear envelope, and 1 to 2 clumps in the central area (Fig. 6C). Under TEM, the large clumps are made up of tightly packed 30-nm chromatin fibers, while 10-nm fibers are distributed in the nucleoplasm around the heterochromatin blocks (Figs. 14D, E; Table 1). The cytoplasm has similar features as those in the previous stages (Figs. 14C, F).

### **Spermiogenic Cells and Spermatozoa**

There are ten stages of spermatids ( $St_{1-10}$ ) depending on the size, nuclear shape and chromatin condensation pattern.

**Spermatid stage 1 ( $St_1$ )** This cell is about 15  $\mu\text{m}$  in size and has round-shaped nucleus (about 6-7  $\mu\text{m}$  in diameter). Under LM, the nucleus of this cell is smaller than that of spermatocyte, and the cell is located close to the lumen. It is stained light blue with only few small blocks of heterochromatin scattered throughout. The cytoplasm appears pale blue after staining with methylene blue, and also contains numerous mitochondria (Fig. 7A). Under TEM, the chromatin consists almost entirely of euchromatin which exists at 2 levels, *i.e.*, 10 nm and 30 nm (Fig. 15C; Table 1). There are only few small blocks of heterochromatin scattered in the central area of the nucleus. In addition to abundant mitochondria and some ribosomes, the cytoplasm also contains very large Golgi complex with multiple section, each consisting of 3-4 stacks of cisternae, interconnected with the neighbouring sections (Figs. 15B, D-F). This “multisectorial” Golgi complexes show evidence of active secretory activities in the forms of two types of membrane-bound granules at trans-face. These two types of granules consist of the smaller and very dense proacrosomal granule and the

multigranular body which contains numerous dense vesicles within one membranous sac (Figs. 15D, E, F).

**Spermatid stage 2 (St<sub>2</sub>)** This round-shaped cell is about 20x12 µm in size and contains spherical nucleus which is about 5-6 µm in diameter. At LM level, it shows more densely stained nucleus due to increasing amount of heterochromatin (Fig. 7B). At TEM level, the nucleus, which is localized between Golgi complex and the group of mitochondria, is characterized by the thickening of the cephalic part of the nuclear membrane close to the Golgi complex (Figs. 16A-C). This is believed to be the site for adherence of acrosomal vesicle, and is the future apex of condensed sperm within the nucleus. There are patches of heterochromatin spreading throughout, and in the euchromatic area. The chromatin still exists in two sizes, *i.e.*, 10 nm and 30 nm (Figs. 16B, C; Table 1). The Golgi complex remains closely associated with the outer surface of the tentative acrosomal site of the nuclear membrane. This multisectorial Golgi complex still actively synthesizes both types of granules, *i.e.*, the dense proacrosomal granules (Figs. 16D, F), and the "multigranular body", which may be formed by the accumulation of dense core vesicles within a single large membrane sack (Figs. 16D, E).

**Spermatid stage 3 (St<sub>3</sub>)** This cell has about the same size as St<sub>2</sub>, but it contains smaller but still spherical nucleus. Under LM, increasing number of evenly-scattered heterochromatin blocks and patches are observed in the nucleus as dark blue stained bodies (Fig. 7C). Under TEM, the tightly aggregated 30-nm chromatin fibers make up the heterochromatin blocks and patches. Furthermore, the caudal nuclear membrane is also visibly thickened; and a large patch of heterochromatin made of the tight aggregation

of 30-nm fibers were observed to be tightly attached to this caudal the nuclear envelope (Figs. 17A-D; Table 1). Concurrently, there the large Golgi complexes migrate to the caudal part of the cell's cytoplasm and it comes to be localized near the clusters of mitochondria in the same region (Figs. 17A, E, F).

**Spermatid stage 4 (St<sub>4</sub>)** This cell becomes oval in shape (about 20x11  $\mu\text{m}$ ) and the nucleus begins to be flattened on the caudal side facing the large group of mitochondria, where the nuclear envelope is markedly thickened with condensing chromatin mass, while the remaining chromatin appears lighter and has uniform density throughout the nucleus (Fig. 7D). Under TEM, the nucleus still contains 10-nm and 30-nm chromatin fibers (Figs. 18B-D; Table 1). At the cephalic and caudal parts of the nuclear membrane, the 30 nm fibers are aggregated in increasing amount causing these areas of the nuclear envelope to appear thicker and denser (Figs. 18A-D). The cytoplasm shows progressive migration to the caudal part of the cell and becomes more elongated, and the Golgi complexes are migrating further to the caudal end of the cytoplasm and is separated from the nucleus by a large group of mitochondria (Figs. 18E, F, G).

**Spermatid stage 5 (St<sub>5</sub>)** This cell shows the nucleus which is highly flattened, with the caudal side more indented. Thus, the nucleus is transformed into oblong shape with the size about 2x7  $\mu\text{m}$ . At LM level, the nucleus gradually migrates to the cephalic pole of the cell which assumes a comet shape (Fig. 7E). When observed under TEM, the chromatin, which comprises mostly of 30-nm fundamental fibers (Figs. 19 A, B; table 1), is evenly distributed, but becomes denser because of the decrease in size of the nucleus. The thickened caudal nuclear envelope shows the implantation fossa at the indented

region in which the centriole is lodged and becomes tightly linked with the caudal nuclear membrane. This is the beginning of the tail formation, while the rest of the tail which consists of the axoneme extends from the distal centriole. The clusters of mitochondria are observed surrounding the axoneme (Fig. 19A, B).

**Spermatid stage 6 (St<sub>6</sub>)** This cell has similar features as St<sub>5</sub> except the nucleus is gradually compressed in the cephalo-caudal direction to become a curved disc. Under LM, the nucleus is stained intensely blue due to the evenly condensed chromatin (Fig. 8E). Under TEM, the random-coiled 30-nm chromatin fibers gradually straightened into smaller filaments about 20 nm in diameter that corresponds to level 3 (Figs. 19C, D; Table 1). These chromatin fibers are dispersed throughout the nucleoplasm and are more tightly packed hence the nucleus appears denser. The developing acrosome can be found at the cephalic pole of the nucleus (Figs. 19E, F), while the tail has extended further from the centriole (Fig. 19C).

**Spermatid stage 7 (St<sub>7</sub>)** The nucleus is bent further to assume an arrow- or boomerang-like shape (about 3×7 μm) (Figs. 7F, 8A). At LM level, the chromatin is highly condensed and appears more intense in comparison to the preceding stages. The cytoplasm is lightly stained, while the dense granulated structures which assume to be mitochondria become concentrated in the caudal cytoplasm around the forming tail (Fig. 7A). At TEM level, the conformation of 20-nm chromatin fibers (level 3) in St<sub>6</sub> changes from partially coiling to assume the straight-parallel conformation (level 4), with each chromatin fiber about 14 to 16 μm in thickness; and these fibers seem to extend in

parallel from the caudal to the cephalic parts of the nuclear envelope (Figs. 20A, B, C; Table 1).

**Spermatid stage 8 (St<sub>8</sub>)** The nucleus of this stage has a pear shape due to the “pulling in” of the wings of the arrow-shaped nucleus of St<sub>7</sub> (Figs. 20D, E, F) similarly to the folding of an umbrella. Under LM, the nucleus is stained dark blue, and in the concavity of the caudal side of the nucleus the centriole becomes the proximal part of the tail which exhibits marked elongation (Fig. 8B). Under TEM, the nucleus shows completely straight chromatin fibers (level 4) which extend in the parallel conformation from the caudal to the cephalic parts of nuclear membrane (Figs. 20E, F; Table 1). The connecting piece of the tail is completely formed and appears as the crystal-liked structure around the centriolar-axonemal complex, while the remaining portions of the tail are still growing and developing.

**Spermatid stage 9 (St<sub>9</sub>)** This cell has a paddle-like shape. Its nucleus starts to elongate with increasingly tapered anterior end to become cone-like shape. Under LM the nucleus is stained to the same intensity as in the preceding stage, while the cytoplasm is stained light blue (Fig. 8B). The tail is filled with numerous mitochondria which are concentrated around the axoneme; and the Golgi complexes are translocated to the most caudal end of the cell which still has a considerable mass of cytoplasm. As revealed by TEM, the straight-paralleled chromatin fibers (level 4) are closely packed to become large parallel bundles each measured about 110 to 117 nm in width (Figs. 22B-F; Table 1). Each bundle consists of 7 to 10 fibers tightly packed together, and separated from other bundles by light narrow channels (Figs. 22B, C). However, there are still a few

isolated level 4 straight fibers. This stage shows the almost complete formation of the tail which is recognizable by many structures that ensheath the axoneme (Fig. 21).

In the present study, the tail complex of stage 9 spermatid could be divided into 6 levels according to the cross sectional characteristics (Fig. 21). The first level is the region of the base of the nucleus which is indented by the centriolar core (Figs. 22D, E). The second level consists of the crystal-like structure surrounding the centriolar-axoneme core (Figs. 22D, F). The third level is composed of 4-5 layers of mitochondria derivatives that are surrounding the axoneme-fibrous sheath complex (Figs. 23A, B). The fourth level is equivalent to the mid-piece of mammalian sperm and consists of the segment of the tail surrounded by 4 layers of mitochondria derivative (Figs. 23C, E). The fifth level shows the reduction of mitochondria derivative to one layer around the axoneme-fibrous sheath complex (Figs. 23D, E). The sixth level passes through the caudal most end of the tail where the Golgi complex is reduced in size but still remains in the multisectorial fashion (Figs. 23F, G; 24A). During the formation of the complex tail of stage 9 spermatid, there may be a newly formed mitochondria where membrane are derived from the Golgi complex. These newly formed mitochondria exhibiting mitochondrial sheaths wrap around the axoneme fibrous sheath complex of the tail (Figs. 24A-F).

**Spermatid stage 10 (St<sub>10</sub>)** This cell has a long slender shape with the size about 6x2  $\mu\text{m}$ . Its nucleus is elongated to form a spindle-shaped head which is still embedded in the cytoplasm of the Sertoli cell cytoplasm. The excess cytoplasm (residual body) of the cell is released from the head and remains only at the caudal part of the cell (Fig. 8C).

Under TEM, the chromatin consists of thick bundles, each measured about 110 to 120 nm in width (Figs. 25D-F; Table 1). And each bundle is composed of closely packed 7-10 level 4 straight fibers.

The acrosome is now completely formed at the most anterior tip extending beyond the nucleus (Figs. 25A-C). It looks like a dense cup fitting over a dense cylindrical rod which represents the anterior tip of the sperm head. The cell membrane covers the entire acrosomal complex (Figs. 25A-C). Thus the tail is completely formed (Fig. 8D).

**Spermatozoa (Sz)** There are 2 stages of spermatozoa: Sz<sub>1</sub> is the immature spermatozoon that begins to show highly elongated nucleus with dense chromatin, a very small acrosome which is not visible in semithin sections, and a very long helical tail without surrounding cytoplasm (Fig. 8E). Under TEM the nucleus shows dense chromatin that exists in crystalline-like lattice, in which the individual fiber appears as straight line about 10 nm in width, separated from its neighbor by the intervals 3-4 nm in width. However, in Sz<sub>2</sub>, there are still some oval lightly-stained spaces left in the nucleus (Figs. 26A-D).

The mature spermatozoa (Sz<sub>2</sub>) are aggregated in a large group embedded in the cytoplasm of the Sertoli cells (Figs. 8E; 27A). The nucleus is fully elongated and slightly tapered at the anterior end with the size about 6x1  $\mu\text{m}$ . Under LM, the spermatozoon shows fully elongated and falciform-shaped nucleus (about 1x7  $\mu\text{m}$  in size) with completely dense chromatin, and it has a very long tail which lacks the surrounding cytoplasm. At TEM level, although the nucleus is homogeneously dense, the crystal-

lattice-liked conformation could still be observed. Each space between the crystal lattice is at constant length about 3-4 nm (Figs. 27B, D; 28B-E).

The tail of mature spermatozoon represents one of the most complex structure among the animal sperm's tail. Along its entire length, the tail consists of two columns of cytoplasm and axoneme-fibrous sheath complex twisted around each other in helical formation along the long axis (Figs. 25A; 26A). Therefore, the tail could be divided into eight levels based on the structures that surround the axoneme and the cross sectional profiles.

The first level ( $L_1$ ) is the neck region which is the top portion of centriolar core. This level shows the centriolar core of the flagellum surrounded by homogeneous structure which filled up the inner portion of implantation fossa at the base of nucleus (Figs. 27E, F).

The second level ( $L_2$ ) is located below  $L_1$  and consists of the crystal-like structures around the axoneme-fibrous sheath complex, with the latter consisting of nine longitudinal dense rods (Fig. 26C-E; 27E, F).

The third level ( $L_3$ ) contains the most caudal part of the nucleus and concentric lamellae of mitochondria derivatives of mitochondria surrounding axial complex filament (Figs. 28C-F; 28E; 29A-C). There is the beginning of cytoplasmic column nearby (Fig. 28E; 29A).

The fourth level ( $L_4$ ) is the mid-piece of the tail (Figs. 18D, E; 29D, E), which shows 4-6 layers of concentric lamellae of mitochondria derivative around the axial

complex and the cytoplasmic column surrounded by mitochondria derivatives around containing glycogen on one side of the axial complex (Figs. 29D, E).

The fifth level ( $L_5$ ) has only one layer of mitochondrial derivatives. Within the cytoplasmic column, there are numerous glycogen granules (Figs. 30A-D). The cytoplasmic column is filled with glycogen granules (Figs. 30A-D).

The sixth level ( $L_6$ ) has similar features as  $L_5$ , but there is no mitochondria layers. The fibrous sheath around the axoneme is also absent but the axonemal complex and the cytoplasmic column is surrounded by 2-3 layers of fence-like cylindrical sheath (Figs. 30D, E).

The seventh level ( $L_7$ ) is similar to  $L_6$ , but it is characterized by the disappearance of the cytoplasmic column (Fig. 30 G).

The eighth level ( $L_8$ ) is the last portion of the tail which consists of the axoneme covered only by the plasma membrane (Fig. 30H).

### **Sertoli Cell and Follicular Cell**

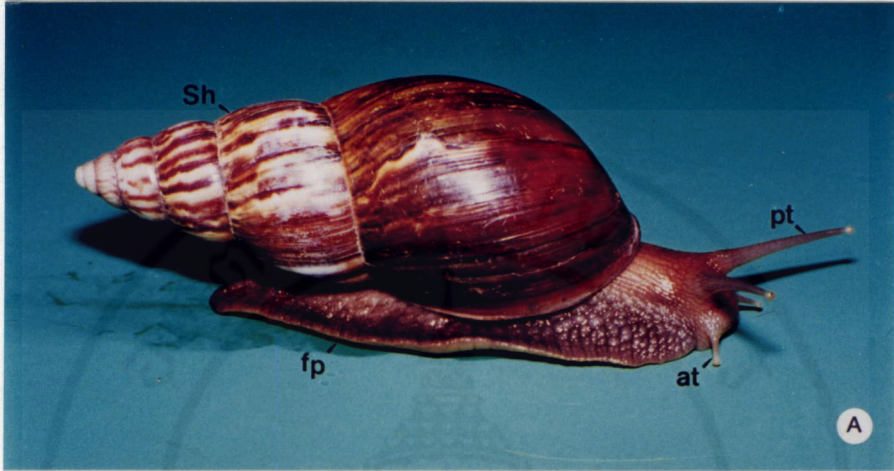

Sertoli cell is the largest cell in the ovotestis, and it could be easily distinguished by the large round nucleus with regularly arranged heterochromatin patches (Figs. 8A; E, 31A-C). The cytoplasm contains numerous lipid droplets and few large dense granules (Fig. 8E). When observed under TEM, these dense heterochromatin patches are scattered evenly throughout, and there is a deep indentation at one side of the nucleus (Figs. 31A, C). The cytoplasm is branched into long processes: the basal processes maintain continuous contact with the follicular cells and the basal lamina, and the apical processes

extend to the lumen of the ovotestis' tubules, and some are in contact with spermatocytes and spermatids. Numerous organelles that appear include lysosomes, abundant rough endoplasmic reticulum, large amount of mitochondria, and a relatively small Golgi complex (Figs.31C-F).

The follicular cell is located on the basal lamina adjacent to the Sertoli cells (Figs. 32E, F; 33A, B). It has an ovoid nucleus with thin strip of heterochromatin lining the inner surface of the nuclear envelope, and small blocks scattered in the center of nucleoplasm. The cytoplasm shows moderate amount of mitochondria and many small granules consisting of a dense core surrounding by light halo ring. It also has long processes of cytoplasm, that together with the processes of the Sertoli cell, line on the basal lamina of the tubules (Figs. 32A; E, F; 33A-C). Thus, the cellular sheet lining the basal lamina is composed of the cytoplasmic processes of Sertoli cells interdigitated with each other, and with those of the follicular cells (Figs. 32A; 33C-F). Invariably, the long processes of the Sertoli cell's cytoplasm usually cover the long cytoplasmic processes of follicular cells. Hence, this cellular sheet separates spermatogenic cells from the basal lamina. The final maturation of spermatids also takes place in the cytoplasm of Sertoli cells. Occasionally, desmosome can be seen between spermatocytes, spermatids and Sertoli cells (Fig. 32C).

**Figure 1.** Surface anatomy of *Achatina fulica*

- A) Photomicrograph of an adult *A. fulica* in the late rainy season showing shell (sh), foot process (fp), and 2 cephalic tentacles, *i.e.*, anterior (at) and posterior (pt).
- B) Photomicrograph of an adult *A. fulica* in the early rainy season showing shell (sh), foot process (fp), 2 cephalic tentacles, *i.e.*, anterior (at) and posterior (pt), and prominent penis at the common genital pore (co).
- C) An adult snail is feeding on a fruit in the early rainy season.

**Figure 2.** Copulation of *A. fulica*

A, B) Photomicrographs of two adults *A. fulica* in the early rain season showing their muscular penis (pe) which are everted and inserted into the vagina of their partners.

Copyright by Mahidol University

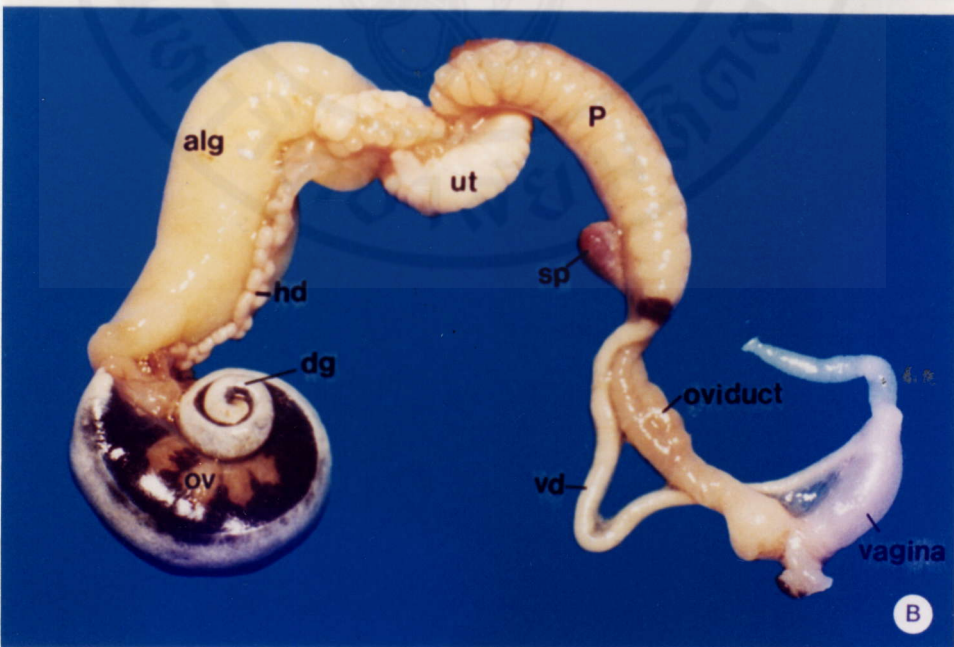

**Figure 3.** Gross anatomy of *A. fulica*

- A) Photomicrograph of a giant land snail after removal of the coiled shell. The ovotestis (ov) appears yellow in color, and is embedded and mixed with the coiled digestive gland (dg) at the caudal part. It is connected with the albumen gland (alg) via the hermaphroditic duct (hd). The cephalic part in A. also shows the retracted head (he) and the foot process (fp).
- B) Macro photograph of the same specimen showing the ovotestis (ov) embedded in the coiled digestive gland (dg), hermaphroditic duct (hd), and albumen gland (alg).

**Figure 4.** The reproductive system of *A. fulica*

- A) Photomicrograph of *A. fulica* after removal of the shell and mantle showing the visceral organs. (alg-albumen gland; dg-digestive gland; hd-hermaphroditic duct; P-prostate gland; vd-vas deferens; ov-ovotestis)
- B) Further dissection of the body showing that the reproductive system is divided into male and female pathways. The male pathway consists of the prostate gland (P), vas deferens (vd), and penis (pe) located in the common genital opening. The female pathway mainly consists of the uterus (ut), oviduct, and vagina that is connected to the same genital opening. (dg-digestive; sp-spermatheca)

**Figure 5.** Photomicrographs of *A. fulica* stained with hematoxylin and eosin (H&E), and with methylene blue (MB)

- A, B, C) Paraffin sections of the ovotestis of *A. fulica* showing tubules (Sm) containing both developing male germ cells (Sc, St, Sz) and female germ cells (Oc). The center of each tubule is filled with the tails of spermatozoa. Tubules are separated by loose connective tissue containing fat cells (fa), and parts of the digestive glands (dg) are located within the same vicinity.
- D) Semithin section of a tubule of an ovotestis showing germinal epithelium consisting of developing male germ cells (Sc, St) and packets of spermatozoa (Sz), and a female germ cell (Oc).

**Figure 6.** Semithin sections of *A. fulica*'s tubules stained with MB showing various stages of cells in spermatogenesis:

- A, B) Spermatogonia are the smallest cells ranging from those that have clear nuclei with prominent nucleoli and thin rims of pale blue or slightly basophilic cytoplasm (Sg-in A) to those that are larger with nuclei having lace-like heterochromatin, prominent nucleoli and increased amount of basophilic cytoplasm (Sg-in B).
- C) Leptotene primary spermatocytes (LSc), each showing dense dots of heterochromatin scattering throughout the nucleus which still contains small nucleolus. The cytoplasm has light basophilia and contains a large member of mitochondria (arrow). Secondary spermatocytes (SSc) exhibit clumping of heterochromatin into large blocks along the nuclear envelope and in the center of the nuclei.
- D) Zygotene primary spermatocytes (ZSc), each exhibiting thicker blocks of heterochromatin which become cord-like. The nucleolus is sizable (arrow).
- E) Pachytene primary spermatocytes (PSc), each showing intertwining thick chromatin cords and very prominent nucleolus (arrow). (T-tail, Sz-spermatzoa)
- F) Diplotene primary spermatocytes (DSc), each exhibiting small nucleus with closely packed thick cords of chromatin.
- G, H) Diakinetic primary spermatocytes (DiSc), each showing large and fewer pieces of chromosomes that are moving to be aligned in a row at the equatorial region in metaphase spermatocyte (MSc-in H and F).

**Figure 7.** Semithin sections of *A. fulica*'s tubules stained with MB during early spermatids:

- A) The nucleus of stage 1 spermatid (1) is much smaller than in PSc and SSc but is still round and contains fine granules of heterochromatin. The cytoplasm is lightly basophilic and contains numerous mitochondria (arrow).
- B) In stage 2 spermatid (2), the nucleus is decreased in size and appears denser, while becoming more eccentrically-located. The main mass of cytoplasm moves to one side and contains numerous mitochondria (mi) as well as a very large Golgi complex (gc).
- C) In stage 3 spermatid (3), the nucleus is decreased further in size but nucleoplasm becomes denser and contains larger blocks of heterochromatin. The cytoplasm contains large Golgi complex (gc) and numerous mitochondria.
- D) In Stage 4 spermatid (4), the nucleus becomes uniformly dense with one side marked by thickened chromatin mass along the nuclear envelope (arrow). The cytoplasm assumes an oval shape and contains numerous mitochondria (mi) in tight cluster.
- E, F) In stage 5 spermatid (5), the nucleus assumes flat disc and is translocated to one side of the cell, and the trailing cytoplasm contains numerous mitochondria (mi). In stage 6 spermatid (6), the nucleus is more oblong and assumes a curved disk-shape, while in stage 7 spermatid (7) the nucleus becomes opaque due to the fully condensed chromatin, and it assumes an arrow or boomerang-shape. (Oc-oocyte)

**Figure 8.** Semithin sections of *A. fulica*'s tubules stained with MB showing late spermatids:

- A) Stage 7 spermatid (7) showing boomerang-shaped nucleus with completely condensed chromatin and numerous mitochondria (mi) in the trailing cytoplasm.
- B) Stage 8 spermatid (8) showing cone-shaped nucleus with completely condensed and opaque chromatin, and the long tail sprouting out from the nuclear fossa (arrow). Mitochondria (mi) become concentrated around the tail (T) and Golgi complexes (gc) move to the caudal end of the trailing cytoplasm.
- C, D) Stage 9 spermatid (9-in C) showing a dense oval-shaped nucleus with the opaque chromatin. The tail (T) is fully lengthened and surrounded by numerous mitochondria. Golgi complex is much decreased in size. In stage 10 spermatids (10-in C and D), the anterior end of the completely opaque nucleus becomes pointed and slightly curved.
- E) Fully mature spermatozoa (Sz) showing elongated and falciform-shaped nuclei which are completely opaque. The tails (T) become cylindrical and devoided of the cytoplasmic mass. Groups of spermatozoa have their heads embedded within the apical cytoplasm of a Sertoli cell (SE), which is the largest cell whose nucleus contains uniform patches of heterochromatin, and the cytoplasm contains numerous lipid droplets (ld) and a few dense granules (arrow). (Nu-nucleus)

**Figure 9.** Classification of cells in *A. fulica*'s tubules under TEM

- A) TEM micrograph of the basal part of the tubules showing that the Sertoli cell (SE) has the largest nuclei containing scattered heterochromatin (hc) and a prominent nucleolus (no) and it is located on the basement membrane (bm). In the nearby area, there are the follicular cells (fc) with oval nucleus and cytoplasm rich in mitochondria (mi).
- B) An adjacent area showing spermatogonia (Sg) whose round-shaped nuclei contained mostly euchromatins.
- C, D) Higher magnifications showing prominent nucleolus surrounded by thin zigzag 10 nm (1) and 20 nm (2) whose cross sections appear as dense dots of heterochromatin.
- E, F) A nearby area in the cytoplasm showing developing rough endoplasmic reticulum (rer), small amount of mitochondria (mi), and small Golgi complex (gc).

**Figure 10.** Electron micrographs of leptotene primary spermatocyte

A, B) The early leptotene primary spermatocyte (LSc) showing the round nucleus (Nu) and the cytoplasm containing increasing number of mitochondria (mi) and larger Golgi complex (gc).

C-F) Another of leptotene stage showing a large nucleus with prominent nucleolus (no), and the first appearance of dense lines that form axis of chromatin condensation (ax). In E. and F., the chromatin fibers exist 2 levels: the thin zigzag 10-nm fibers (1) and 30-nm fibers whose cross sections appear as dense dots (2). Small blocks of heterochromatin are formed by the tightly packed 30-nm fibers. In F. the axis of chromatin condensation is surrounded by a tight aggregation of 30-nm fibers (2).

**Figure 11.** Electron micrographs of zygotene primary spermatocytes

- A, B) Zygotene primary spermatocytes (ZSc) showing the nucleus with increasing density of heterochromatin, and longer axis of chromatin condensation and synaptonemal complex (sy) that could not be found in the previous stages.
- C, D) High magnifications showing the axis of chromatin condensation (ax) and the chromatin that still appear in 2 sizes: 10 nm (1) and 20 nm (2) fibers.
- E, F) High magnifications the appearance of tripartite structure of synaptonemal complex showing a conspicuous central element separated from and paralleled to the two lateral elements. In F. shows that the nucleolus (no) is still fairly prominent as in LSc.

**Figure 12.** Electron micrographs of pachytene primary spermatocytes

A-C) Pachytene primary spermatocytes, each showing smaller sizes of the nuclei (Nu) with still fairly prominent nucleoli, and the heterochromatin (hc) becomes condensed into long thick threads.

D, F) At high magnification, these chromatins show a dense interconnected clumps of heterochromatin (hc). The 10 nm fibers (1) and 30 nm (2) fibers are also shown in D and the cytoplasmic organelles in F. show the larger size of Golgi complex (gc), mitochondria (mi) and RER (rer).

**Figure 13.** Electron micrographs of diplotene and diakinesis primary spermatocyte

- A, B) Diplotene primary spermatocyte (DSc) showing the smaller sized nucleus with more tightly packed heterochromatin. The cytoplasm also shows the increasing size of Golgi complex (gc) and the clusters of mitochondria (mi) which are scattered around the cell.
- C, D) The nucleus of this cell has more heterochromatin than euchromatin; and chromatin fibers also exist 2 sizes, i.e., 10 nm and 30 nm fibers (1, 2 respectively). Figure C. shows that packing of chromatin occurs at the nuclear envelope (NE). Figure D. shows that the packing also occurs in the central area.
- E, F) Diakinesis primary spermatocyte (DiSc) showing large blocks of heterochromatin that are parts of the completely formed chromosome (ch). The cytoplasm consists of RER and mitochondria (mi) which are seen around the nucleus.

**Figure 14.** Electron micrographs of metaphase primary spermatocyte and secondary spermatocyte

A, B) Metaphase primary spermatocyte (MSc) containing large blocks of heterochromatin which are pieces of chromosomes (ch). In B., the chromatin blocks are formed by a tight aggregation of 30-nm fibers. There are large amounts of mitochondria (mi) in the cytoplasm.

C-F) Secondary spermatocyte (SSc) whose nucleus contains large clumps of thick chromatin (hc) scattered throughout and attached to the nuclear envelope (NE). The chromatin each still maintains the sizes of 30-nm (2) and 10-nm chromatin fibers. The cytoplasm contains similar features as in the preceding stage. High magnification of these cells are also shown in E. and F.

**Figure 15.** Electron micrographs of stage 1 spermatid

- A, B) Stage 1 spermatid ( $St_1$ ) whose nucleus shows mostly distributed euchromatin, and small heterochromatin blocks are drizzly scattered. The cytoplasm shows numerous mitochondria and very large Golgi complexes, which are arranged in “multisectorial” structure located on one side of the cell. Large amounts of mitochondria are also seen.
- C) At high magnification, there are still 2 levels of chromatin are still observed: 10-nm fibers of level 1 (1) and 30-nm fibers of level 2 (2).
- D, E, F) High magnification micrographs of multisectorial Golgi complexes showing clearly active synthetic activities in forming 2 types of granules, *i.e.*, proacrosomal granules (pg) and multigranular bodies (mb). In D and E. the mitochondria show many long cristae.

**Figure 16.** Electron micrographs of stage 2 spermatids

- A, B, C) Stage 2 spermatid ( $St_2$ ) whose nuclei are located between Golgi complex (gc) and the clusters of mitochondria (mi). The nucleus shows thin layers of electron dense material on a part of nuclear envelope (arrow) which suppose to be the future acrosomal surface. The chromatin still exists in 2 two sizes, *i.e.*, 10-nm (1) and 30-nm (2) coiled fibers as shown in B. and C. At the cephalic part of the nucleus, there is a acrosomal granule (Ac) which is still developing.
- D, E, F) Higher magnifications of the giant “multisectorial Golgi complexes” (gc) that still show active secretory-synthetic activities: proacrosomal granules (pg) and multigranular body (mb).

**Figure 17.** Electron micrographs of a stage 3 spermatid

A-D) Stage 3 spermatid ( $St_3$ ) whose nucleus (Nu) migrates eccentrically to one side that is assumed to be the cephalic part. Acrosomal surface (black arrow) also shows thicker layer of electron dense nuclear envelope at the cephalic part. The 30-nm fibers (2) are mostly found and begin to aggregate at the caudal part of nucleus (white arrow). The 10-nm chromatin fibers (1) still exist in the nucleoplasm. Details of the cephalic and the caudal part of the nucleus are shown in C and D, respectively.

E,F) High power micrographs showing the stacks of very large Golgi complexes (gc) and many numerous mitochondria (mi).

**Figure 18.** Electron micrographs of stage 4 spermatids

- A-D) A stage 4 spermatid showing the nucleus (Nu) which become flatten from the caudal side facing a large groups of mitochondria (mi). The cephalic part of the nucleus shows the predicted acrosomal surface (black arrow), while the caudal part shows a marked line for differentiation of the tail (white arrow).
- C, D) High magnifications showing the thickening with chromatin mass on the cephalic (black arrow in C.) and the caudal parts (white arrow in D) of nnuclear membrane. The chromatin consists of mostly 30-nm fibers (2) and a small amount of 10-nm fibers (1).
- E) Low-magnification micrograph of a stage 4 spermatid showing a large amount of mitochondria (mi) located between the nucleus and the very large Golgi complexes.
- F, G) High magnifications of the giant multisectorial Golgi complexes (gc) which are still active and show the proacrosomal granules (pg), and membrane-bound dense granules in the trans-face area. In E., there are also other granules called multigranular bodies (mb).

**Figure 19.** Electron micrographs of stage 5 and stage 6 spermatids

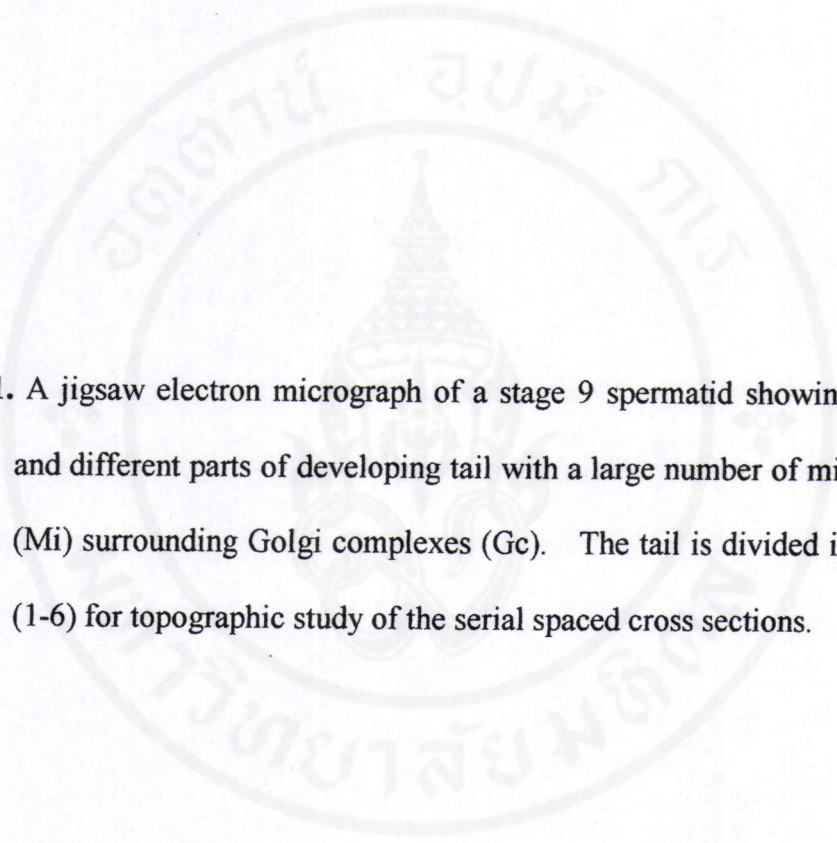

- A, B) A stage 5 spermatid ( $St_5$ ) showing the nucleus (Nu) which is highly flattened, and is transformed into oblonged shape. At the base of the nucleus, there is fossa that contains the centriole (ce) which is elongated to form the tail. A large number of mitochondria (mi) are seen to surrounding the axoneme of the tail. The chromatin exists only one size, 30-nm fibers (2) that make the nucleus uniformly dense.
- C, D) A stage 6 spermatid ( $St_6$ ) whose nucleus (Nu) is gradually compressed in cephalo-caudal direction to become a curved disc and is more condensed. The cytoplasm also shows the cross section of the axoneme which is surrounded by a large number of mitochondria. In D., the chromatin fibers within the nucleus are gradually elongated into filaments about 20-nm fibers (3) equal to level 3 in table 1.
- E, F) Another stage 6 spermatid showing the developing acrosome with cylindrical rod and is surrounded by two unknown materials located at the top of the triangular-shaped nucleus (Nu).

**Figure 20.** Electron micrographs of stage 7 and stage 8 spermatids

- A, B) A stage 7 spermatid (St<sub>7</sub>) showing nucleus (Nu) which has an arrow- or boomerang-like shape and is densely stained. The chromatin shows transformation to straight parallel fibers (4 in B.) which extend from the inner surface of nuclear envelope at the caudal part to the cephalic part of the nucleus. The mid-piece (mp) of the tail, which consists of 9+2 doublets of axoneme microtubules shown in cross section, is located between two wings of the nucleus at the caudal portion. It is surrounded by numerous mitochondria.
- C) Longitudinal section of a stage 7 spermatid, showing an arrow-like nucleus containing the chromatin which become straight-parallel fibers (4). The centriole (ce) is tightly embedded in the implantation fossa and continuing with the axonemal flgellum.
- D) A stage 8 spermatid (St<sub>8</sub>) showing a pear-like nucleus (Nu) with the chromatin consisting of straight-parallel fibers (4), and the centriole at the base. The cytoplasm contains moderate amount of mitochondria (mi).
- E, F) At high magnification, the straight fibers of chromatin (4) are arranged in the parallel conformation and extend from the inner surface of nuclear envelope (white arrow) at the caudal part to the cephalic part. The completely formed centriole (ce), which consists of crystal-like structure around the axoneme, is embedded within the caudal nucleus.

**Figure 21.** A jigsaw electron micrograph of a stage 9 spermatid showing the head and different parts of developing tail with a large number of mitochondria (Mi) surrounding Golgi complexes (Gc). The tail is divided into 6 parts (1-6) for topographic study of the serial spaced cross sections.

**Figure 22.** Electron micrographs of a stage9 spermatid

- A) The anterior part of a stage 9 spermatid (St<sub>9</sub>) whose nucleus shows highly condensed chromatin with increasingly tapered anterior end that has a cone-like shape. The caudal portion of the nucleus also shows a completely formed centriole which is continuing with the proximal part of the axoneme (Ax) surrounded by derivative structure of mitochondria (mi).
- B, C) Higher magnification of longitudinal sections of the nucleus showing that the chromatin consists of 14-16 nm straight fibers (4) closely packed into the bundles (two-heads arrow). Each bundle is composed of 7-10 fibers tightly packed together. The arranged microtubules (Mt) are seen around the nucleus.
- D, E, F) The head of stage 9 spermatids showing a centriole (ce) which is implanted into the fossa of the caudal nucleus. It is shown in longitudinal section in D., and cross section in E that is regarded as the first part. The second part, consisting of crystal-like structure (arrow) surrounding the axoneme, (Ax) is shown in oblique section in F.

**Figure 23.** Topographic electron micrographs of a stage 9 spermatid

- A, B) The neck level of a stage 9 spermatid, showing the longitudinal section of the third level of the developing tail that consists of the 9+2 doublets of axonemal microtubules surrounded by 4-5 layers of mitochondrial derivative (arrow) and the vacuole containing flocculent substances. The cross section of this level (Fig. B) shows a set of parallelly-arranged microtubules (Mt) that are seen around the mitochondrial derivatives.
- C) The fourth level of the tail segment showing the axoneme (Ax) surrounded by about 4 layers of mitochondrial derivative (arrow).
- D) The fifth level of the tail showing the (9+2) axonemal microtubules (Ax) which are surrounded by a group of mitochondria. The cross sections of the fourth and the fifth parts of the tail are shown in E.
- F, G) The sixth level of the cell showing very large Golgi complexes that still remain at the caudal portion of the cell and many modified mitochondria (mi).

**Figure 24.** Transformation of mitochondria in the middle piece of stage9 spermatids

- A) TEM Micrograph shows the cluster of mitochondria surrounding a cross section of axoneme (Ax); the active Golgi complexes are also seen in this vicinity.
- B, C) Cross sections of the forming tails showing the axoneme surrounded by a few layers of mitochondrial derivative; and a row of microtubules is seen around this mitochondrial sheath. In C, very large Golgi complexes are also shown adjacent to the mitochondria.
- D, E, F) The tail part showing mitochondrial derivatives (arrow) with their long inner membrane. The cristae become rearranged to form several layers of parallel concentric rings around the axoneme (Ax).

**Figure 25.** Electron micrographs of the head of stage 10 spermatid

- A) A stage 10 spermatid ( $St_{10}$ ) showing a slender nucleus (Nu) which occupies the head, and is composed of more condensed chromatin. Surrounding the most anterior tip of the nucleus is the acrosome (Ac) which is completely formed at this stage. (PM-plasma membrane)
- B, C) Completely formed acrosome (Ac) consists of the cylindrical rod covered by a dense cup.
- D, E) At high magnification, the chromatin shows dense bundles which represent closely packed 14-16 nm straight chromatin fibers. (Mt-microtubules)
- F) A cross section through the nucleus and the centriolar core (ce) showing the increasingly condensed chromatin radiating from the centriole, and many irregular electronlucent (va) areas. The nucleus is entirely surrounded by a row of microtubules (Mt).

**Figure 26.** Electron micrographs of the head of the immature spermatozoa

A) The immature spermatozoa ( $Sz_1$ ) whose nucleus contains almost completely condensed chromatin (Nu). Only small electronlucent areas (va) are present. (ce-centriol; Mt-microtubules)

B-E) High magnification micrographs showing that each bundle (110-120 nm) of chromatin (ch) from the precedent stage becomes homogeneously condensed and leave only small electronlucent (va) areas. (cross section in-C. and oblique section in-E.)

**Figure 27.** Electron micrographs of the mature spermatozoa

A-D) Anterior parts of mature spermatozoa ( $Sz_2$ ) showing completely condensed and electron opaque chromatin in elongated nuclei (Nu).

F) Spaced serial cross sections of the proximal levels of the tails ( $L_1, L_2, L_3$ ) showing axoneme surrounded by nearby structures.

**Figure 28.** Topographic electron micrographs of the head and connecting piece of mature spermatozoa

A) Cross sections of the completely formed spermatozoa's tail are shown.

Sperm's tail is divided into 7 levels ( $L_{1-7}$ )

B, C, D) Longitudinal section of the spermatozoa ( $Sz_2$ ) showing the centriolar core that consists of crystal-like structure (arrow) and the axoneme (Ax). At High magnification in C, a rhomboid crystalline-substance (arrows) is shown.

E) Cross sections of the tail segment ( $L_2, L_3$ ). Level 2 ( $L_2$ ), consists of the axonemal microtubules (9+2) surrounded by crystalline-like structure of the centriolar core. This level is at the lower part of spermatozoa's head. Level 3 ( $L_3$ ) shows the similar features to  $L_2$  except that the vacuole containing granular substances is seen juxtaposed to the axoneme.

**Figure 29.** Topographic electron micrographs of connecting piece and mid-piece of mature spermatozoa

- A, B, C) High magnifications of cross sections of the tail in level 3 ( $L_3$ ) showing the axonemal (9+2) microtubules surrounded by a longitudinal column of dense fibrous sheath. It is juxtaposed to the mitochondrial derivatives and the vacuole containing granular substances. This level in A. is at the lowest part of spermatozoa's head (Nu). (Mt-microtubules)
- D, E) Cross sections of level 4 ( $L_4$ ), showing the mitochondrial derivatives (arrows) that form concentric 4-5 layers around the axonemal microtubules. (mi-mitochondria; PM-plasma membrane)

**Figure 30.** Topographic electron micrographs of the mid-piece and end piece of the mature spermatozoa

A, B) Level 5 of the tail showing decreasing concentric rows of mitochondria derivative that form helix containing glycogen-like material (G). (Long section in A. and cross sections in B. and C.)

D, E, F) Level 6 of the tail ( $L_6$ ), showing the features that are similar to those of level 5 ( $L_5$ ), but they are entirely slim down until the next level.

G) The level 7 ( $L_7$ ) consists of the axonemal complex surrounded by 2 or 3 layers of cylindrical sheaths. The helical formations containing glycogen-like material completely disappeared.

H) The distal end of the tails ( $L_8$ ), each showing only an axonemal core (Ax) surrounded by the plasma membrane (PM).

**Figure 31.** Electron micrographs of Sertoli cells in tubules of the ovotestis

A, B) The Sertoli cell has a nucleus characteristically exhibiting a deep indentation and containing small heterochromatin blocks scattered throughout. It has long processes of cytoplasm orientated in contact with the basement membrane (bm). Numerous rough endoplasmic reticulum (rer) and some mitochondria are shown in B.

C-F) At high magnification, its cytoplasmic contents are composed of small Golgi complex (gc), moderate amount of mitochondria (mi), and large amount of RER (rer) located in close association with the nucleus. In addition, lysosomes (Ly) are seen as membrane-bound organelles containing diverse particulate material which is extremely electron dense.

**Figure 32.** Electron micrographs of the basal compartment of tubules of the ovotestis

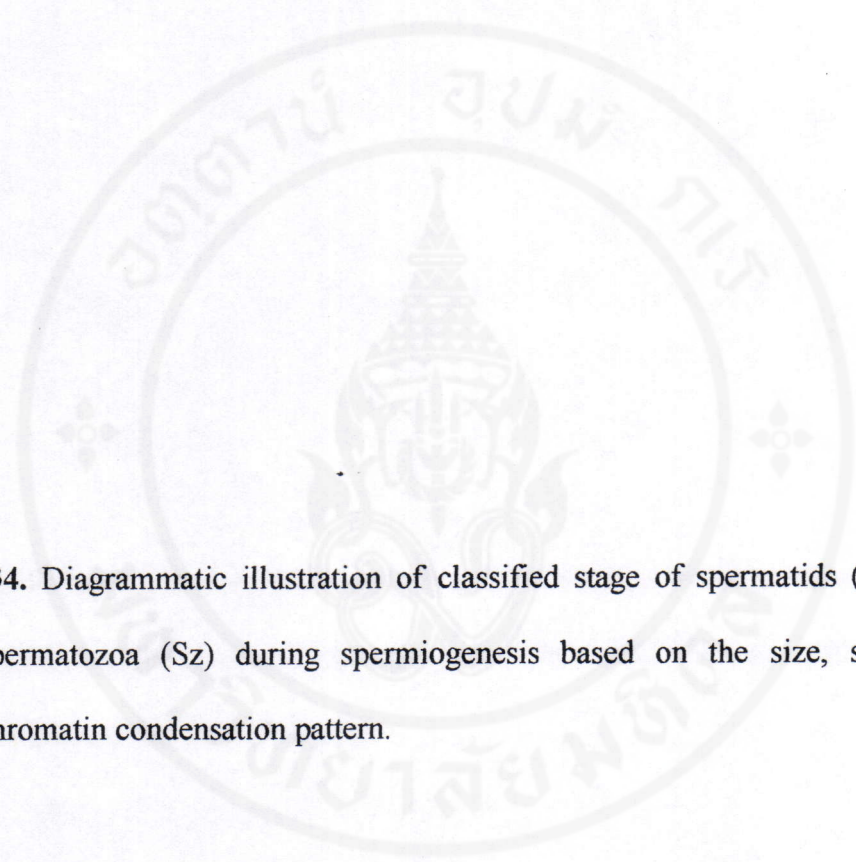

- A) Electron micrograph shows the relationship of the Sertoli cell (SE) and follicular cell (fc) located above the basement membrane to the cells of spermatogenic units (Sc). They formed “haemolym-testis barrier” which functions to prevent the exposure of the gametes to passages of noxious substances.
- B, C, D) The Sertoli cell is postulated to provide structural and metabolic support for the developing spermatogenic cells (Sc). It is bounded to the gamete cells by the septate desmosome. Fig. D. show that the Sertoli cell still envelops the heads (Nu) of many stage10 spermatids (St<sub>10</sub>).
- E, F) Electron micrographs showing the follicular cell which rests on the basement membrane (bm), and is covered by the cytoplasm of the Sertoli cell (SE). The follicular cell (fc) has an oval nucleus containing thin strips of heterochromatin (hc) along the inner surface of nuclear envelope, and some small irregular blocks scattered centrally.

**Figure 33.** Electron micrographs of follicular cells in tubules of ovotetis

- A) High magnification showing that follicular cell (fc) is located between the long process of Sertoli cell (SE) and the basement membrane (bm). Its nucleus (Nu) contains thin strip of heterochromatin (hc) along the inner surface of nuclear envelope, and some small-scattered heterochromatin.
- B, C, D) The follicular cell (fc) show cytoplasm branching between the cytoplasmic processes of Sertoli cell (SE) and the basement membrane (bm). Note that the cytoplasm of the other Sertoli cell (cy) can be observed penetrating under the cytoplasm of the follicular cell. The junction between follicular cells is shown in D.
- E, F) Low magnification shows the association of the structures that form "haemolym-testis barrier" in the ovotestis. This structure is composed of the cytoplasm of Sertoli cell (SE), cytoplasm of follicular cell (fc) and basement membrane (bm). (Mu-myoid cell)

**Figure 34.** Diagrammatic illustration of classified stage of spermatids ( $St_{1-10}$ ) and spermatozoa (Sz) during spermiogenesis based on the size, shape, and chromatin condensation pattern.

**Table 1:** The dimension of chromatin fibers in the nuclei of various stages male germ cells in the ovotestis of *A. fulica*. Straight fibers (level 4) usually form lamellae or bundles, each about 110-120 nm thick, and are coalesced together to become opaque mass in the mature spermatozoa. Finally, the level 5 fibers exist in the crystal-lattice-liked structure with regular spacing about 3-4 nm.

\* The diameter of twenty chromatin fibers in EM negatives taken from at least five nuclei of each cell stage were measured by using a Nikon profile projector.

Male germ cells in <i>A. fulica</i> ovotestis	Chromatin fibers (diameter ± SE)					
	N*	Level 1 (coiled fibers)	Level 2 (coiled fibers)	Level 3 (semi-coiled)	Level 4 (straight fibers)	Level 5 (Crystal lattices)

## CHAPTER VI

### DISCUSSION

#### Gonadal Histology

The gonad of *Achatina fulica*, unlike those of other gastropods and bivalves (50, 51, 52, 53, 54), do not have delimiting fibrous capsule. The gonadal tissue is mixed with the hepatopancreatic tissue within the same connective tissue bed. However, gametogenesis is carried out within the circumscribed tubules which are surrounded by the thick basement membrane. Perhaps, this barrier together with an, as yet, unidentified gonadal-hemolymph barrier could provide the sequestered environment for the specialized meiotic division as occurring in vertebrates (55, 56). Despite the presence of the germ cells of both sexes within the same tubule, the cellular association of male germ cells is generally similar to the germinal epithelium in the seminiferous tubules of vertebrates' testes (57, 58, 59, 60, 61, 62), *i.e.*, the early staged germ cells are disposed toward the periphery of the tubules, with spermatogonia and some early primary spermatocytes (LSc) attached to the surrounding basement membrane. Eventhough oogonia and oocytes appear lying next to the groups of developing spermatocytes, they are in fact completely partitioned from the latter by a thin wall formed by the flat sheets of follicular and Sertoli cells, which could help to create the special mileu for oogenetic and spermatogenic processes apart from the main tubular microenvironment. Eventhough both types of sex cells are present, the ovotestis of a single snail either has a male-dominated or

female-dominated phases. In the former, the proliferation of male germ cells is actively occurring, while the female germ cells remain dormant in oogonia and Oc<sub>1</sub> stage, and vice versa for the female-dominated gonad. Genetic and/or environmental factors that control the expression of sexual dimorphism of this hermaphroditic snail remain to be elucidated.

## **Spermatogenesis**

Generally, the stages of cells in spermatogenesis are similar to those of other mollusks and vertebrates. However, there is only one stage of spermatogonia, whose cytoplasmic characteristics are indicative of cells which are preparing themselves for the forthcoming synthetic activity. Sg has large and sometimes more than one nucleoli, and intensely basophilic cytoplasm. Under TEM, it was demonstrated that the cytoplasm of Sg is rich in polyribosomes but with only few mitochondria, rough endoplasmic reticulum, and slender Golgi complex. These characteristics imply that this cell is actively engaged in ribosomal synthesis, while there is no secretory activity. The presence of abundant heterochromatin blocks also suggests that there is still probably a low level of transcriptional activity in producing mRNA. Subsequent stages of primary spermatocytes exhibit the pattern of heterochromatinization similar to those in other gastropods (25, 26, 63) and vertebrates (61, 64). It seems, therefore, that these developmental steps of the first meiosis and the mechanism of heterochromatinization in male germ cells of animals are evolutionarily conserved. In *A. fulica*, as in higher vertebrates, the varying forms of the heterochromatin from LSc to DSc and MSc is brought about by the increasingly tighter aggregation of 30-nm nucleosomal-type fibers (27; see Table 1), even though the molecular mechanism that

brings about this tight packing is not understood. It is interesting to note that the axis of chromatin condensation which appears as a single dense line is present in LSc; and their number is increasing in ZSc which also have the synaptonemal complexes, which are differentiated from the former by the tripartite structure. The two chromosomal accessory structures are similar to that of the vertebrates' LSc and ZSc (64, 65) axis of condensation may be involved in the initial condensation and packaging of 30 nm chromatin fibers into the chromosomes. Later, this structure may transform into proteinaceous scaffold forming the axis of each chromosome as reported previously (65, 66). On the other hand, the synaptonemal complex may play similar role as those found in vertebrates' spermatocytes, that is in pairing the homologous chromosomes together and initiating the process of crossing over.

In PSc, as a result of chromatin condensation around the axes, large blocks of heterochromatin are formed and they become evenly distributed throughout the nucleus. It is noticeable that there is no heterochromatin lining on the nuclear membrane which is probably due to the complete retrieval of all chromatin fibers to be wound into dense blocks around the axes. After this stage the heterochromatin blocks transform into large and fewer pieces of chromosomes in DSc and DiSc. After MSc, the two halves of the chromosomes are segregated and the daughter SSc are formed. And like in mammals, SSc is extremely few in number which implies that this stage may pass through quickly; in contrast to spermatogenesis in bivalves (40, 41, 67) and in primitive gastropods (36, 50, 53), in which there are quite numerous SSc which imply the longer transit time for SSc stage.

## Spermiogenesis

The many diversified stages of male germ cells during spermiogenesis in *A. fulica* represent a complex variation of the same theme as those observed in higher vertebrates especially mammals. In order to achieve fairly drastic change in shape, complete chromatin condensation, acrosomal and tail formations, the developing spermatids have to pass through at least ten identifiable morphological stages in comparison to twelve stages in mouse and nineteen stages in rat (60, 61, 68), in contrast to only four stages in bivalves and primitive gastropods (25, 69, 70, 71). In 1991, Sretarugsa and coworkers (12) studied the spermiogenesis in *A. fulica* and classified spermatids into four stages based on their shape, chromatin appearance, and distribution of organelles. In the present study, we have further investigated the spermiogenesis in *A. fulica* and classify the spermatids into ten stages. The change in shape of the spermatid's nucleus during its differentiation to spermatozoon represents one of the most remarkable examples of spermiogenesis, where the nuclear configuration transforms from spherical or ovoid to flat disc, and later boomerang or arrow-liked shapes whose "wings" could be folded together to form the pear-liked shape that eventually transforms to the falciform shape. It is remarkable to note that when SSc stage transits to St<sub>1</sub> the originally dense chromosomes of SSc are "reorganized" again by being decondensed into evenly dispersed 10 and 30 nm fibers (see Table 1), while the Golgi complex is transformed to the "giant" multisectorial structure with clearly increased synthetic activities (Figs. 14B-F). It is possible that St<sub>1</sub> needs to form this very large secretory organelle not only for producing the proacrosomal granules but also for forming other granules of unknown function, such as multigranular bodies (Fig. 14E), and possibly the membrane of specialized

mitochondria that are wrapping around the proximal end of the sperm's tail (Figs. 23A-F). The "reorganization" of chromatin in  $St_1$  may be correlated with these synthetic activities, which may need a large amount and varieties of mRNA that must be derived from the once again highly decondensed chromatin. This feature is similar to mammalian spermiogenesis when proacrosomal granules begin to be formed in the early spermatids, in contrast to lower gastropods and bivalves in which the granules are presynthesized early in primary spermatocytes, and the already dense chromatin of SSc tends to condense further and transform into dense mass in the early spermatids (26, 40, 41, 67, 72). Like in mammals after  $St_1$  that 30-nm chromatin fibers start to condense again into increasing larger heterochromatin blocks in  $St_2$  and  $St_3$ . The cephalic part of the nuclear membrane is thickened and it serves as the site where proacrosomal granules are later assembled. Interestingly, the caudal part of the nuclear membrane is also thickened in  $St_3$ , and this domain of nuclear membrane induce the preferential chromatin condensation along its inner surface. In  $St_4$  the 30-nm fibers become homogeneously condensed throughout the nucleus except for the area close to the caudal part of the nuclear membrane where the chromatin remains denser. In comparison to 30 nm chromatin fibers, the 10-nm fibers are rapidly decreased in quantity until they disappear completely in  $St_6$ . The Golgi complexes, meanwhile, are still very prominent and maintain their multisectorial configuration and highly active synthetic activities until  $St_6$  or  $St_7$ . Chromatin begins to change noticeably again in  $St_6$  where the fibers is reduced in size to about 20 nm which is the only level of chromatin organization found in this stage (see Figs. 18C, D; Table 1). These fibers also are much denser than 30-nm fibers in earlier spermatids and appear less coiled. Eventually they transform in  $St_7$  and  $St_8$  into straight fibers running

parallel course from the thickened caudal part to the cephalic part of the nuclear membrane (see Figs. 19 A-F; Table 1). In St<sub>9</sub> and St<sub>10</sub> the straight fibers start to form bundles, each about 110 to 120 nm in width. Initially, these bundles are separated from each other by large pale-stained channels devoided of chromatin material. Eventually, they are fused together to form completely electron opaque mass in Sz<sub>2</sub>, which is the fully mature spermatozoa. However, at high magnification and resolution the dense chromatin in Sz<sub>2</sub> still appear as crystal lattice structure with each dense line about 10 nm thick and the lattice space about 3-4 nm. Thus, the DNA packing in the male germ cells of *A. fulica* present a unique pattern where the 30 nm supposedly nucleosomal-type fibers are transformed to the more rigid and straight fibers of reduced size (20 nm), that become laterally associated into crystal-like tight packing. Since the profiles and changes of the basic nuclear proteins (histones and/or protamine-like proteins) have not yet been studied in this species, it is not possible to conclude whether these proteins play any role in the tight packing. However, it is clear that this fibrous to bundle type packing is quite different from the fibrous to granular type or fibrous to toroidal type packing as reported in higher mammals and human (73, 74). Whether the changes in chromatin fiber sizes and their aggregation have direct influence on the head transformation remained to be proven.

In contrast to mammals, the formation of acrosome, as visualized by light microscopy and TEM, is not prominent. Proacrosomal granules appear to be synthesized in St<sub>1</sub> when the Golgi complexes become highly enlarged to the multisectorial structure. The dense vesicles continue to be produced well into St<sub>5</sub> and begin to assemble at the mid-point of the cephalic part of the nuclear membrane in St<sub>6</sub> (see Figs. 18E, F). The acrosome is fully formed in St<sub>10</sub> where it appears as a dense

cup fitting over the dense cylindrical anterior tip of the sperm head (see Figs. 24A, B, C). It is covered externally by the plasma membrane which also covers the remaining part of the head. There appear to be little cytoplasm remaining around the head of the sperm, a row while row of microtubules exist around the nucleus even in the fully mature spermatozoa (see Figs. 27A-E).

In comparison to the acrosome, the formation of the tail could be easily followed. Beginning from stage 5, the tail rudiment could be detected in the concavity of the highly flattened nucleus where mitochondria gravitate to surround it. Earlier electron microscopic study by our group indicated that the tail of *Achatina fulica* is accorded with strong fibrous sheath akin to the tails of vertebrates' and higher mammals' sperm, which is the characteristic of the internally-fertilizing spermatozoa (29, 32, 75, 76). The present TEM studies of the tail formation reveal even more intricate details of the sperm's tail in this mollusk. In St<sub>8</sub> and St<sub>9</sub>, while the wings of the nucleus are pulled inward to form the pear-shape nucleus, the most proximal portion of one centriole projects deep into the caudal end of the nucleus (level 1). The centriolar core is surrounded by the thickened caudal membrane derived from St<sub>5</sub> and St<sub>6</sub>, from which the straight chromatin fibers are attached (see Figs. 19E, F; 21E, 24F). Below this centriolar core the centriolar microtubules are surrounded by a rhomboid shape crystalline substance (level 2) that may help to anchor the "wings" of the nucleus together, as well as contributing to the sturdiness of the proximal part of the tail. This crystalline mass is a unique feature not seen in other mollusks and vertebrate species. Below the crystalline mass is the parts of the tail which is equivalent to the mid-piece of vertebrates' sperm (level 3, 4, 5), where the nine columns of dense fibrous sheaths surround the axonemal complex akin to

those found in mammalian sperm (47, 75, 76). Four to five rows of specialized mitochondria form concentric layers around the axoneme-fibrous sheath complex (Figs. 22A-E). This mid-piece slims down distally due to the decrease in number of rows of mitochondria which eventually disappear (level 6). The redundant Golgi complex is relegated to the distal end of the tail which appear bulbous and contains still a considerable amount of cytoplasm (see Figs. 20, 22F, G).

In  $St_{10}$  and maturing spermatozoa the major modification is on the distal end of the tail where the cytoplasmic mass is lost, and the tail consists of the axonemal complex surrounded two or three layers of fence-like cylindrical sheaths disposed at regular intervals (level 7). Finally, the end piece (level 8) consists of only the axonemal core surrounded by the plasma membrane. From level 3 downward to level 5 the axonemal-fibrous sheath complex exists side-by-side in helical formation with the column of clear cytoplasm that contains glycogen-like material. Both are surrounded in turn by the cylindrical sheaths. The presence of abundant glycogen deposit within this clear cytoplasmic column may provide reserve energy for the axonemal movement. In other words, spermatozoa of *A. fulica* may depend more on glycolysis to yield energy for its movement than in vertebrates and mammalian spermatozoa that receive ATP mostly from the Krebs's cycles in the mitochondria (47, 48, 76).

The close association of developing spermatids with Sertoli-like cells was observed, especially at stage 10 and immature spermatozoa when their heads are embedded within the apical cytoplasm of the Sertoli cells. This implies that Sertoli cells may play a more complex role in supporting and controlling the spermatids' differentiation. In contrast, in more primitive gastropods and bivalves, the earliest

stages of spermatids are already detached from the germinal epithelium, and the subsequent differentiation and cellular morphogenesis appear to occur independently in each developing spermatid (36, 40, 53). Indeed, the Sertoli cells in *Achatina fulica* ovotestis are very large and appear to have very complex cytological features similar to that of Sertoli cell in the mammalian testes (77, 78). Apart from its role in nurturing spermatids and spermatozoa, Sertoli cells may be the major component of hemolymph-testis barrier since their basal cytoplasm also branch out into thin sheets that, together with the branches of flattened follicular cells, form the complex interdigitation that completely line the basal lamina (see Figs. 31E, 32A-F). Thus, through this rather tight barrier the internal environment of the ovotestis tubules may be kept isolated from the hemolymph.

From the aforementioned characteristics of developing male germ cells, the multi-stage spermatids and their close and prolonged association with the Sertoli cells, we believe that spermiogenesis of *A. fulica* represents an evolutionarily advance step from other mollusks which progresses more toward the mammalian patterns.

## CHAPTER VII

### CONCLUSIONS

The ovotestis histology and ultrastructure of the male germ cells in *Achatina fulica* were studied by light and electron microscopy. Classification of male germ cells and the organization of chromatin during spermatogenesis and spermiogenesis were also concluded:

#### Ovotestis Histology

*Achatina fulica*'s gonad contains both male and female germ cells, hence it is called "ovotestis", which is located at the apex of a coiled shell. It consists of numerous small tubules, each of which contains various stages of male and female germ cells, Sertoli cells, and follicular cells which help to segregate oogenetic cells from spermatogenic cells. Each stages of spermatogenic cells is found aggregating in groups and make up the main mass of the germinal epithelium of each tubules, while clusters of spermatozoa existed close to the tubular lumen.

#### Cells in Spermatogenesis & Chromatin Condensation

The male germ cells during the process of spermatogenesis and spermiogenesis can be classified into 20 stages according to the cell size, shape, ultrastructural features and the chromatin condensation. Spermatogenic cells consist of spermatogonium (Sg), six stages of primary spermatocytes (PrSc), i.e., leptotene

(LSc), zygotene (ZSc), pachytene (PSc), diplotene (DSc), diakinesis (DiSc) and metaphase (MSc) spermatocytes, secondary spermatocyte, ten stages of spermatids (St<sub>1</sub>-St<sub>10</sub>), and two stages of spermatozoon (Sz<sub>1</sub>-Sz<sub>2</sub>). Sg has the feature of a stem cell, i.e., the presence of mostly euchromatin and few small heterochromatin blocks in the nucleus and prominent nucleolus. LSc and ZSc contain increasingly large heterochromatin blocks that could be condensed by the axis of condensation which appear as a single dense line, and cross-linked by synaptonemal complexes, the tripartite structure. These heterochromatin blocks are transformed into larger and fewer pieces of chromosome in DSc and DiSc. Finally, in MSc the paired chromatids are arranged along the cells' equatorial region. Following MSc stage, the two halves of chromosomes are segregated and daughter SSc are formed. SSc shows large clumps of heterochromatin along the nuclear envelope and in the central area; and this cell stage is rarely observed.

### **Spermiogenic Cells and Spermatozoa**

Spermatids display ultrastructural characteristics as follows: spermatid stages 1-4 (St<sub>1-4</sub>) have round nuclei which become progressively smaller. The chromatin of St<sub>1</sub> exhibits the reorganization of dense chromosome from SSc into evenly distributed euchromatin containing 30-nm and 10-nm fibers. Moreover, St<sub>1</sub> shows very large Giant "multisectorial" Golgi complex indicating increased synthetic activities. Chromatin start to condense in to short blocks in St<sub>2</sub> and St<sub>3</sub>. St<sub>2</sub> shows the thicken nuclear membrane at the cephalic part that is the site where proacrosomal granules will adhere. In St<sub>3</sub> the caudal part of the nuclear membrane is also thickened and could be the site of induction of further condensation of chromatin in later stages. In

St<sub>4</sub>, the 30-nm chromatin fibers become homogeneous condensed throughout the flattening nucleus. St<sub>5</sub> nucleus is highly flattened in cephalo-caudal direction and the chromatin remains dense with decreasing amount of 10-nm fibers. These fibers completely disappear in St<sub>6</sub> whose nucleus is curved into a disc shape. Furthermore, in St<sub>6</sub> the chromatin begins to be reduced in size to about 20 nm and begin to be straightened. The Golgi complexes still maintain their multisectional configuration and have highly active synthetic activities. St<sub>7</sub> nucleus has an arrow or boomerang-shape, which is transformed to pear shape in St<sub>8</sub>. The chromatin in St<sub>7</sub> is transformed to straight fibers as well as reduced in size to about 14-16 nm in diameter. These fibers appear much denser in St<sub>7</sub> and St<sub>8</sub>, and extend in parallel from the thickened caudal part to the cephalic part of the nuclear membrane. In St<sub>9</sub> and St<sub>10</sub>, the nuclei start to elongate with increasingly tapered anterior end, while the straight chromatin fibers are aggregated into become bundles 110-120 nm in width. The chromatin bundles are separated from each other by the irregular electronlucent area devoided of chromatin material, and they are fused in Sz<sub>1</sub>. Sz<sub>2</sub> into completely the opaque chromatin mass which, at high resolution, that appear as parallel 10 nm dense lines quit similar in conformation with crystal lattice structure with the lattice interval of 3-4 nm.

### **Acrosome Formation**

Proacrosomal granules begin to be synthesized in St<sub>1</sub> when the Golgi complex becomes highly enlarged to the multisectional structure, and they are produced from St<sub>1</sub> to St<sub>5</sub> when they begin to be coalesced on the mid-point of the cephalic part of the nucleus. In St<sub>10</sub>, the acrosome appears as a dense cup fitting over the dense

cylindrical rod at the anterior tip of the sperm's head which is covered externally by the plasma membrane.

### **Tail Formation**

The tail of *A. fulica* sperm is a highly complex structure and can be divided into 8 levels (L<sub>1</sub>-L<sub>8</sub>) according to the ultrastructural characteristics of the cross sectional profiles. L<sub>1</sub> is formed by centriolar core that deeply projects into the nucleus and surrounded by the thickened and highly invaginated caudal nuclear membrane; this occurs in St<sub>5</sub>. The axoneme of the flagellum is growing in St<sub>6</sub> and is surrounded by a large number of mitochondria. In St<sub>7</sub>, the tail further elongates and completely formed in Sz<sub>2</sub>. At L<sub>1</sub> of the tail is the part of the centriolar core surrounded by the thickened caudal membrane. At L<sub>2</sub> consists of the centriolar microtubules surrounded by a rhomboid shaped crystalline substance. At L<sub>3</sub> and L<sub>4</sub>, the axonemal microtubules are surrounded by a longitudinal column of fibrous sheath that is in turn covered by concentric rows of mitochondrial derivatives. At L<sub>3</sub> to L<sub>5</sub> which correspond to the mid-piece, the tail slims down distally due to the decrease of numbers of layers of mitochondria which evenly disappear at level 6. From level 3 to level 5 the axonemal-fibrous sheath complex exists side-by-side in helical formation with column of clear cytoplasm containing glycogen-like material. At level 7, the longitudinal fibrous sheaths disappear, and the axonemal complex is surrounded by two or three layers of fence-like cylindrical sheaths with regular intervals. Level 8, is the end piece, the axonemal core is surrounded only by the plasma membrane.

## **Sertoli Cell and Follicular Cell**

Sertoli cell is the largest cell located on the basement membrane of the ovotestis' tubule. It has a large round nucleus with deep indentation, and contains evenly scattered patches of heterochromatin. The cytoplasm contains abundant organelles such as Golgi complex, mitochondria and RER. The apical branch of Sertoli cells embrace developing spermatocytes, spermatids and spermatozoa, while their basal branch form thin sheets that interlace with branches of follicular cells, to form the complete lining over the basal lamina. This composite structure could serve as the haemolymph testis barrier.

The follicular cell has flattened nucleus containing mostly euchromatin, and only a few clumps of heterochromatin along the nuclear envelope. The cytoplasmic organelles are sparse. Their cytoplasmic processes also branch out into thin slender sheets that interdigitate with those of adjacent follicular cells and Sertoli cells. This basal follicular cell may form part of the haemolymph-testis barrier, while other may form covering of the oocytes that help to segregate female from male germ cells.

## APPENDIX

### 1. Solutions for Paraffin Technique

#### Fixatives: Bouin 's solution

picric acid (saturated aqueous)	75	ml
40% formaldehyde	25	ml
glacial acetic acid	5	ml
add 0.14 M sodium chloride (MW 58.44)		

#### Staining Solutions

##### 1. Harris' s Hematoxylin Solution

hematoxylin crystals	5	g
ethyl alcohol, 95%	50	ml
potassium or ammonium alum	100	ml
single distilled water	950	ml
mercuric oxide	2.5	g
glacial acetic acid	40	ml

##### 2. Alcoholic Eosin Solution

eosin-y	2	g
single distilled water	160	ml
ethyl alcohol, 95%	640	ml

## 2. Solutions and Embedding Media for Semithin Technique

**Fixatives:** 1. 4% glutaraldehyde plus 2% paraformaldehyde in 0.1 M sodium cacodylate buffer

2. 1% osmium tetroxide in 0.1 M sodium cacodylate buffer

### Buffer Solutions

0.2 M sodium cacodylate buffer pH 7.4

sodium cacodylate	4.28	g
single distilled water	100	ml

0.2 M calcium acetate

calcium acetate	0.32	g
single distilled water	10	ml

0.1 M sodium cacodylate buffer pH 7.4

0.2 M sodium cacodylate buffer	96	ml
0.2 M calcium acetate	4	ml
single distilled water	100	ml

### Staining Solutions

1% Methylene blue in 1% Borax

methylene blue	0.5	g
borax	0.95	g
single distilled water	50	ml

**Embedding Media**

Araldite 502 resin	27	ml
DDSA	20	ml
DMP-30	1	ml

**3. Solutions and Embedding Media for TEM****Fixatives:**

- 2.5% Glutaraldehyde in 0.1 M cacodylate buffer, pH 7.4
 

5% glutaraldehyde	5	ml
0.2 M sodium cacodylate	4	ml
0.2 M calcium acetate	1	ml
- 1% Osmium tetroxide in 0.1 M cacodylate buffer, pH 7.4
 

2% Osmium tetroxide	5	ml
0.2 M cacodylate buffer	5	ml

**Buffer Solution**

- 0.2 M sodium cacodylate buffer, pH 7.4
 

sodium cacodylate	4.28	g
single distill water	100	ml
- 0.2 M calcium acetate
 

calcium acetate	3.16	g
single distill water	100	ml
- 0.1 M cacodylate buffer, pH 7.4
 

0.2 M sodium cacodylate buffer	24	ml
0.2 M calcium acetate	1	ml

single distill water	25	ml
----------------------	----	----

**Staining Solutions**

## 1. 5% Uranyl acetate

uranyl acetate	2	g
distill water	40	ml

## 2. Lead citrate

NaOH	2	g
lead citrate	0.25	g
distill water	50	ml

**Embedding Media**

Araldite 502	27	ml
DDSA	23	ml
Accelerator DMP-30	1	ml

## BIOGRAPHY

<b>NAME</b>	Miss Viriya Pankao
<b>DATE OF BIRTH</b>	15 September 1975
<b>PLACE OF BIRTH</b>	Bangkok, Thailand
<b>INSTITUTIONS ATTENDED</b>	Mahidol University, 1993-1997 Bachelor of Science (Physical therapy) Mahidol University, 1997-2000 Master of Science (Anatomy)
<b>RESEARCH GRANT</b>	Thailand Research Fund (TRF) (Senior Research Scholar Fellowship to Prof. Prasert Sobhon)
